HODGKIN'S DISEASE*

I. General Considerations

HENRY JACKSON, JR., M.D.,† AND FREDERIC PARKER, JR., M.D.‡

BOSTON

IT IS the purpose of this and the succeeding articles to give a brief account of the clinical picture of Hodgkin's disease, its treatment and its prognosis, together with such descriptions of the pathology of the condition in its various forms as seem necessary for an understanding of the limits of the entity included under this title. The study is based largely on material collected over a period of years from the Boston City Hospital, the Collis P. Huntington Memorial Hospital, the Pondville Hospital (Massachusetts Department of Public Health) and our private practice. From the Children's Hospital we have added certain data with the permission of Dr. W. E. Ladd.

No attempt will be made to cover exhaustively the extensive and often confusing literature. For a more complete bibliography, the reader is referred to the admirable review of Wallhauser¹ and the later work of Sternberg.²

CLASSIFICATION

In our opinion, Hodgkin's disease can and should be divided into three types—paragranuloma, granuloma and sarcoma.³ We believe that it is essential to recognize the existence of these three forms of the disease, for the pathologic picture, the clinical aspects and the prognosis differ materially with each. We hope to be able to show that this subdivision is of practical value to the clinician as well as to the pathologist. No originality is claimed for such a classification, but it is our belief that it is not so widely recognized and utilized as it should be.

The Germans include in their *Granulomatose* the granulomatous form and also some cases that we classify as sarcomatous. Sternberg did not recognize the paragranuloma type and denied the existence of the sarcoma. Ewing,⁴ however, postulated

the occurrence of the latter arising from the granulomatous type.

It should become clear as this presentation of the pathologic and clinical features of the three types of the disease proceeds that any description that includes all three as a single form of the disease must, of necessity, be inaccurate and of little practical value.

Paragranuloma, granuloma and sarcoma are included as three different types of Hodgkin's disease on the basis of two features. The first is the presence in each of the so-called "Reed-Sternberg" cells. We believe strongly that the diagnosis of Hodgkin's disease cannot be made in their absence. Some authors describe what they term an early form of the disease, characterized by hyperplasia and hypertrophy of the reticulum and endothelial cells without the presence of Reed-Sternberg cells. In our opinion, such a diagnosis is not justified. The second feature is the transformation, with the passage of time, of one type of the disease into another. Thus, a patient may be stricken with what is proved by biopsy to be Hodgkin's paragranuloma, and months or even years later a second biopsy may reveal the presence of Hodgkin's granuloma. Similarly, a granuloma may become a sarcoma, or much more rarely the two forms are found coexisting in the same patient or, exceptionally, in the same node. It should be emphasized in this connection that we have never encountered what might be termed a reverse transformation—that is, a Hodgkin's sarcoma reverting to a granuloma, or a granuloma regressing to a paragranuloma. What we regard as the most benign form may and frequently does progress into the more malignant one. The reverse never occurs.

Historical Summary

Hodgkin's paragranuloma. Hodgkin's paragranuloma first appeared in the literature under the unfortunate name "early Hodgkin's."⁵ To be sure, this type is often early in the sense that it is, in

*From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard) and the Mallory Institute of Pathology, Boston City Hospital, the Department of Medicine, Harvard University, and the Pondville Hospital, Massachusetts Department of Public Health.

many cases, a precursor of the more rapidly advancing granulomatous type, yet patients with Hodgkin's paraganuloma may live unembarrassed by their disease—if the pathologic picture does not change—for many years. One patient (L. C., S36-1256) is living and active thirty-eight years after the first proved lymph-node involvement, although the condition, as shown by multiple biopsies, is still present. The term "early" under such circumstances is hardly an apt one. Therefore the designation "paraganuloma" has been introduced, the prefix indicating "in close relation to." So far as we are aware, this exact designation has not been used elsewhere in the literature.

Hodgkin's granuloma. We confine the term "Hodgkin's granuloma" to the type familiar to all. There is probably no other disease to which so many different names have been applied. Wallhauser¹ in his excellent review mentions more than fifty terms that have appeared. Such a state of affairs renders a study of the literature, and particularly the older literature, extremely difficult and has unquestionably caused much confusion and misunderstanding in the minds of students of the disease. The multiplicity of terminology is undoubtedly due to a lack of knowledge of the true nature of the condition.

In 1865, Wilks⁵ suggested the name "Hodgkin's disease." In addition to this term, the most widely used and most generally accepted are lymphadenoma,⁶ malignant lymphoma,⁷ malignant granuloma,⁸ lymphogranuloma⁹ and scirrhus lymphoblastoma.¹⁰ The *Index Medicus* used the term "Hodgkin's disease," whereas the *Quarterly Cumulative Index* listed the disease under lymphogranuloma until 1941, when the term "Hodgkin's disease" was reinstated.

Few diseases have been given a clear-cut, comprehensive and definitive description by the investigator who first brought them to the attention of the medical profession. Hodgkin's granuloma is no exception to this rule. In 1832, Thomas Hodgkin¹¹ described 7 cases with generalized lymphadenopathy and splenomegaly and noted that "as far as could be ascertained from observation, or from what could be collected from the history of the cases, this enlargement of the glands appeared to be a primitive affection of those bodies, rather than the result of an irritation propagated to them from some ulcerated surface or other inflamed texture through the medium of their inferent vessels." Hodgkin was further arrested by the state of the spleen, which in all but one case was found more or less diseased and in some cases was "thickly pervaded with defined bodies of various sizes in structure resembling that of the diseased glands." He concluded that there was "a close connection between the derangement of the glands and that of the spleen," and he believed that the latter was "a posterior effect and on this account may not

always have been produced, when that of the glands or some other disease carried off the patient."

It is true that among Hodgkin's original cases there were probably but 3, at most 4, of the condition that now bears his name,¹² and it has been the custom, from time to time, to belittle his contribution as uninspired and uninspiring. It would seem juster to acknowledge that the nineteenth-century physician recognized a disease entity at a time when pathology was in its infancy and when the microscopic examination of tissues was virtually unknown.

Hodgkin's contribution seemed, nevertheless, to have been lost sight of until 1856, when Sir Samuel Wilks¹³ described a number of cases of "lardaceous disease." He wrote with chivalrous honesty that on the completion of his paper he had chanced to meet with the observations of Hodgkin in the seventeenth volume of the *Medico-Chirurgical Transactions*, and lamented that "Doctor Hodgkin did not affix a distinctive name to the disease." But, even so, it was not until 1865 that Wilks⁵ really clarified the clinical entity by describing 15 cases, "13 of which resembled in all particulars the first 4 [*sic*] which Mr. Hodgkin first brought under the notice of the profession." At that time, Wilks apparently recognized even more clearly than did Hodgkin that among conditions affecting "the lymphatic glands and the spleen" there was a distinct and separate pathologic entity, for he wrote: "This disease of Hodgkin is clearly separable from lardaceous disease, from cancer, and tubercle, although these affections may bear a relation to one another. It is, however, as much a disease sui generis as any other and deserves a description of its own." Wilks noted the generalized lymphadenopathy, the splenomegaly and the not infrequent involvement of the liver, kidneys and lungs. He drew particular attention to the "remarkable anemia," and it is clear that he separated the condition sharply from the leukemias.

Knowledge of the condition was, however, still in a nebulous state, and it was not until 1878 that Greenfield¹⁴ described, insofar as he was able with the equipment of his day, not only the gross but also the microscopic appearance of the involved tissues. Greenfield evidently used the terms "Hodgkin's disease" and "lymphadenoma" interchangeably, for concerning his second case, one of "lymphadenoma," he wrote, "On section, the spleen presented very typically . . . the condition usually found in Hodgkin's disease." "In all five cases," he added, "the change in the gland was of the same kind. It consisted essentially in a sort of chronic inflammation involving especially the fibrous stroma of the glands which became thickened and gradually obliterated entirely the interstices so that the gland became a mass of dense, tough, fibrous tissue with little or no adenoid structure. . . . In the early stages, there was some general enlargement of the

glands, the fibrous stroma appeared coarser and there were a large number of multinucleated cells adherent to the trabeculae." In a similar manner, he reported: ["The normal structure of the spleen] in the affected parts appears to be entirely lost; it is everywhere traversed by irregular broad bands of fibrous tissue, which in many parts looks as much like sections of tendons as anything. At their edges, and in small places left between them are seen cells of various sizes massed together, a good many large multi-nucleated cells being amongst them."

Greenfield, too, distinguished Hodgkin's disease from leukemia. "In all five cases of typical lymphadenoma here shown," he wrote, "the blood was examined and no increase whatever of leucocytes observed, so that as far as my own experience in ten cases is concerned, I have no ground for believing in the presence of leucocythemia in typical cases of Hodgkin's disease."

Thus, Greenfield in 1878 first brought to the attention of pathologists the increase of fibrous tissue and the presence of multinucleated giant cells. He further noted that "clinically the disease, when well marked, exhibits an irregular febrile course, periods of latency and progress, a marked and peculiar anemia."

A further chapter in the histopathology of the disease was written by Goldmann,¹⁵ who in 1892 noted the frequent presence of eosinophils in the diseased tissue. In 1898, Sternberg¹⁶ discussed at great length what he believed at that time to be a peculiar form of tuberculosis masquerading as "pseudoleukemia," and described in detail the characteristic giant cells and the areas of necrosis. Thus, by 1898 both the main clinical features and the chief histologic findings had been elucidated and Hodgkin's disease had emerged as a definite and clearly recognizable entity.

It remained for Reed¹⁷ in 1902 and Simmons¹⁸ in 1903 to place the knowledge of the condition on a still firmer footing by their accurate and careful studies of the pathological findings in conjunction with the clinical histories. Reed concluded her study in 1902 by saying:

We believe, then, from the descriptions in the literature and the findings in eight cases examined, that Hodgkin's disease has a peculiar and typical histological picture, consisting of proliferations of the endothelial and reticular cells, formation of lymphoid cells and characteristic giant cells and a gradual increase of connective tissue, resulting in fibrosis and, in most of the specimens, in the presence of great numbers of eosinophils.

It must, perhaps, remain a matter of personal choice whose name should be assigned to the ever-present and diagnostic giant cells. Without doubt, they were recognized by Greenfield in 1878, and their characteristics were fully depicted by Sternberg in 1898, but Sternberg had the misfortune to study a series of cases of Hodgkin's disease combined with active tuberculosis, and only in his later years did he give up the idea that he was dealing

with a peculiar form of tuberculosis. Perhaps the greatest credit should go to Reed, who described the cells even more accurately than did Sternberg and who recognized clearly that they were an integral part of the disease described by Hodgkin seventy years before.

Hodgkin's sarcoma. The concept that Hodgkin's granuloma may become transformed into Hodgkin's sarcoma is sometimes traced to Yamasaki,¹⁹ but the histologic descriptions of the "tumor" from his 2 cases in no way substantiate his claim, which is indeed supported solely by the title of his paper. Welch²⁰ reported a case from which a biopsy six months before death showed Hodgkin's granuloma. Autopsy showed widespread involvement by what may well have been a sarcoma developing from a granuloma. Ewing⁴ wrote in 1928, "The transformation of Hodgkin's granuloma into a sarcomatous process occurs in a certain proportion of cases," and added: "The structure varies from a close counterpart of Hodgkin's granuloma to a tissue composed exclusively of large round cells with faintly staining cytoplasm and moderately chromatic vesicular nuclei. Large round giant cells with multiple or multilobed nuclei predominate."

Comparatively few authors refer to this, the most fulminating, form of Hodgkin's disease, although, as Ewing rightly points out, "Many cases described in the literature as lymphosarcoma are probably of this nature."

NATURE OF THE DISEASE

Hodgkin's Paragranuloma

Hodgkin's paragranuloma bears little or no resemblance to a true tumor, either in its histologic picture or its clinical course. The often scattered, isolated Reed-Sternberg cells, the lymphocytic infiltration with or without destruction of the lymph follicles and the complete lack of invasiveness all bespeak an infectious process, as do the comparatively benign course and the fact that in almost all cases the disease starts in the lymph nodes of the neck, to which the causative agent may have gained access through the pharynx. It is not improbable that the paragranulomatous form bears to the granulomatous type of the disease the same relation that a primary tubercle does to fibrocaceous tuberculosis.

Hodgkin's Granuloma

As might be expected from the varied terminology already referred to, opinions concerning the nature of the granulomatous type of the disease are equally at variance. Billroth⁷ and Benda⁸ were firmly convinced that it was a malignant neoplasm. In this country, this concept has been upheld by Warthin,¹¹ Mallory¹⁰ and others. The contrary view—namely, that the condition is an inflammatory or infectious disease and not a neoplasm—has been advocated by Sternberg,² Fraenkel,²² Terplan and Mittelbach²³

and many other workers, both abroad and in this country.

Still another group of authors believe that the granulomatous type represents a combination of an inflammatory and a neoplastic process. Thus, Chevalier and Bernard²⁴ have suggested that it may be an inflammatory reaction due to a virus and that it later changes into a blastoma as do the infectious epitheliomas.

As has been said above, the fact that the Reed-Sternberg cells are frequently scattered, isolated and often separated widely by cells of other types favors an inflammatory process rather than a neoplasm, for certainly in no true tumor does this condition obtain. On the clinical side, the irregular bouts of fever, seldom absent in the more advanced stages and often seen to a less degree early in the course, and more especially the relapsing type commonly called "Pel-Ebstein fever," the marked anemia in absence of bleeding or widespread invasion of the marrow, the polymorphonuclear leukocytosis and the prominent and persistent tachycardia are all more characteristic of an infectious process than of a tumor.

Hodgkin's Sarcoma

Hodgkin's sarcoma has, in our opinion, all the characteristics of a true neoplasm. The uniformity of the cellular constituents, the aggressive, invasive nature of the process, the extremely short duration of life and the not uncommon finding of a large destructive tumor with comparatively few metastases all favor this concept. So also does the fact that the disease is commonest in the sixth and seventh decades and is extremely rare below the age of thirty. This view, however, is contrary to that held by many workers, such as Sternberg² and Kaufmann,²⁵ who maintain that this cellular type is merely a variant of the granulomatous form and is of the same basic nature. As already noted, however, Ewing⁴ speaks of sarcomatous transformation in certain cases of Hodgkin's disease, and we have made similar observations in our own cases.

ETIOLOGY

If our concept of the disease is correct, the etiology of the paragrulomatous form is identical to that of the granulomatous. The granulomatous form is not brought into existence, for the time, owing either to relative immunity on the part of the host or to comparative lack of virulence on the part of the exciting agent.

Historical Summary

Many authors have emphasized the importance of the tubercle bacillus as the etiologic agent in Hodgkin's granuloma. Sternberg¹⁶ originally described the lesion as an atypical form of tuberculosis (8 out of 13 of Sternberg's original series of

cases were complicated by definite tuberculosis). Lichtenstein²⁶ claimed to have produced Hodgkin's granuloma in guinea pigs by the injection of material from human cases and of tubercle bacilli. Fraenkel and Much²⁷ demonstrated antiformin-resistant, gram-positive granules in granulomatous tissue that showed no demonstrable evidence of tuberculosis. Furthermore, by injections of large amounts of antiformin-treated material, they succeeded in producing not only tuberculosis but also lesions that in their opinion resembled those of Hodgkin's granuloma.

L'Esperance^{28, 29} claimed to have shown that the etiologic agent was an avian strain of tubercle bacilli. Her work could not be confirmed by other workers, including van Rooyen,³⁰ Branch³¹ and ourselves.

Perhaps an equal number of investigators have denied the etiologic role of tuberculosis in the production of Hodgkin's granuloma. Both Reed¹⁷ and Longcope,³² whose publications amplified Sternberg's original description of the disease, denied the identity of Hodgkin's granuloma with tuberculosis. Terplan and Mittelbach,²³ as a result of their own experiments and a review of the literature, held the same view. They believed that in those cases in which positive evidence for tuberculosis was obtained, the tubercle bacillus was either a secondary or coincident invader and was in no way causative of the Hodgkin's disease. Furthermore, these authors were not convinced that Hodgkin's granuloma had ever been produced in experimental animals. Uddstromer³³ in his study of 548 cases of Hodgkin's granuloma likewise found no support for the thesis that tuberculosis is the causative agent.

The literature on this particular aspect of the problem is exceedingly extensive, and the reader who wishes further details is referred to the reviews by Wallhauser,¹ Sternberg,² Terplan and Mittelbach²³ and Simonds.³⁴

The tuberculin test has been employed by various investigators in an attempt to prove or disprove a direct relation between the two diseases. Cases of Hodgkin's granuloma have almost uniformly been anergic, reacting, if at all, only to low dilutions — 1:10 or 1:100, rarely 1:1000. The test often becomes positive, frequently strongly so, after effective x-ray therapy.

It should be emphasized that Hodgkin's granuloma is frequently complicated by tuberculosis. According to Ziegler³⁵ and other workers, this occurs in 15 to 25 per cent of cases. In our own series, we found coexistent active tuberculosis in 20 per cent. The fact that one may find in the same patient or even in the same organ both Hodgkin's granuloma and tuberculosis has seemed to us to indicate the lack of identity of the two diseases, for it appears highly improbable, if not impossible, that a host should react in two entirely distinct ways to the

same-micro-organism. Furthermore, if the tubercle bacillus is actually the cause of Hodgkin's granuloma, the disease should be found more commonly in persons suffering from proved tuberculosis than in those free of the disease. Such does not appear to be the case. Medlar³⁶ found Hodgkin's disease in only 0.3 per cent of patients who had tuberculosis and were followed until death at the Metropolitan Life Insurance Company Sanatorium, and of 2297 cases of tuberculosis coming to autopsy at the Boston City Hospital, only 7, or 0.3 per cent, showed Hodgkin's disease as well. This figure is not significantly higher than the general incidence of Hodgkin's granuloma (see below). Furthermore, Uddstromer³⁵ in his careful analysis of the situation in Sweden found that Hodgkin's disease was less common in areas in which the tuberculosis rate was high than in those in which it was low.

Various diphtheroid bacilli have also been claimed as the etiologic agent by a number of investigators. Among these may be mentioned Bunting and Yates,³⁷ DeNegri and Mieremet,³⁸ Bloomfield³⁹ and Torrey.⁴⁰ Bunting and Yates named their organism *Bacterium hodgkini* and claimed that injections into animals produced Hodgkin's granuloma. Others have not been able to confirm their work, however, and numerous investigators have found diphtheroid bacilli in lymph nodes from a variety of other conditions, such as lymphosarcoma, metastatic carcinoma and tuberculosis. It is now generally held that such diphtheroids as have been identified are not of etiologic importance.

It has also been claimed⁴¹ that amebas are the cause of the disease. There has been no confirmation of this claim.

Recently Gordon^{42, 43} in England found that material from Hodgkin's granuloma injected intracerebrally into rabbits produced paralysis that usually resulted in death. Negative results were obtained with the material from cases of carcinoma, sarcoma and with other pathologic tissues. Gordon concluded that this was a satisfactory diagnostic test, and he believed, furthermore, that the disease was due to a specific pathogenic agent, probably a virus, although he was unable to transmit it from rabbit to rabbit. Van Rooyen⁴⁴⁻⁴⁶ confirmed Gordon's results in so far as the test was concerned. In collaboration with Turner, we⁴⁷ demonstrated that the Gordon test is apparently entirely dependent on the presence of eosinophils and is in no way specific for Hodgkin's disease. Our work has been confirmed by Edward,⁴⁸ McNaught⁴⁹ and King.⁵⁰

Another group of workers believes that Hodgkin's granuloma is a special — by some considered allergic — type of reaction of the tissues to any of the usual pyogenic organisms and that the disease, therefore, has no single etiologic agent.

The latest contributions of note on the subject of etiology are those of Parsons and Poston⁵¹ and Wise and Poston.⁵² In the latter paper it is reported

that cultures of lymph nodes from 14 consecutive cases of proved Hodgkin's granuloma yielded positive cultures for organisms of the Brucella group. They further found that such patients were anergic to abortin. Cultures from 67 cases with diseases of lymph nodes other than Hodgkin's disease with one exception yielded negative results. It is as yet too early to pass final judgment on the significance of these findings. To date, we have been unable to confirm them.

Twort⁵³ in an extensive study of the etiology of Hodgkin's granuloma, using a great variety of cultural methods, obtained entirely negative results.

Bacteriologic Studies

For three years, we cultured lymph nodes removed aseptically at surgical operations on an egg medium suitable for growing tubercle bacilli. Approximately seventy-five nodes from patients with a variety of diseases were so cultured. In no case did material from a Hodgkin's granuloma yield a positive culture for *Mycobacterium tuberculosis*, whereas material from tuberculous nodes gave uniformly satisfactory growths of the organism. It should be noted that in 3 cases of Hodgkin's granuloma, smears made from the apparently negative surfaces of the inoculated slants of egg medium showed acid-fast bacilli. These would not grow in subculture, and their nature is entirely obscure.

In addition to the egg medium used, we also cultured the last fourteen nodes of this first series in dextrose ascitic-fluid broth sealed with vaseline, as well as in ascitic-fluid broth and brain broth and on blood agar. Four of the nodes so cultured, three from cases of Hodgkin's granuloma and one from a case of Hodgkin's paraganuloma, yielded a growth of a small gram-positive, strictly anaerobic, gas-forming bacillus. In smears of cultures, the organisms occurred in clumps and chains. Because of this finding and the negative results of our efforts to demonstrate the tubercle bacillus, we discontinued our cultures for the latter and concentrated on culturing for this anaerobic bacillus. For this purpose, we used chopped-meat broth sealed with vascline, a medium that we had found favorable for its growth.

Eighty-one lymph nodes were cultured in this medium. The organism was obtained from a considerable number of cases of Hodgkin's disease but by no means all. It was, however, cultured also from cases with other forms of lymphoma and from nodes involved by carcinoma, tuberculosis and chronic inflammation. A positive blood culture for this organism was obtained from a febrile case of Hodgkin's granuloma (J. A., S36-4092) at the height of the fever, whereas cultures were negative when the temperature was normal. A positive blood culture of a similar organism was, however, likewise obtained from a patient who so far as was known did not have the disease.

Attempts to demonstrate a relation of this organism to Hodgkin's disease by means of agglutination and skin tests failed. The bacillus was not pathogenic for the usual laboratory animals—rabbits, guinea pigs and mice. Its significance, therefore, remains doubtful.

A series of nodes were also cultured in sheep's blood broth and on blood-agar plates and slants, the latter being incubated under normal atmospheric conditions and under increased carbon dioxide tension (10 per cent). The results were consistently negative save for the rare presence of a readily recognized contaminant, such as a staphylococcus. It should be mentioned here in connection with our technical procedure that such contaminations were uncommon.

Animal Inoculations

Portions of the lymph nodes used for culturing for tubercle bacilli were also injected into rabbits, guinea pigs and pigeons. The rabbits were inoculated intravenously, subcutaneously and, rarely, intracerebrally, the guinea pigs intraperitoneally and subcutaneously, and the pigeons intravenously and intraperitoneally. All the animals were kept for from several months up to one and a half years before being killed and autopsied. In the entire group of animals inoculated with material from Hodgkin's granuloma, only one guinea pig showed tuberculosis, the organism proving to be a bovine strain. This node was from a child aged ten years (M. G., S28-1804) and microscopically showed no evidence of tuberculosis, but rather what appeared to be an uncomplicated picture of Hodgkin's granuloma. Nodes from the other forms of Hodgkin's disease and other types of lymphoma as well as carcinomatous nodes and inflammatory nodes gave negative results. As was to be expected, all material from cases of tuberculosis produced that disease in the animals.

Tuberculin Reactions

As reported in a previous paper,⁵⁴ we carried out a series of intracutaneous tuberculin reactions using both human and avian tuberculin. The patients so tested comprised sufferers from a variety of diseases besides Hodgkin's granuloma and included a number known to have active tuberculosis. The patients with Hodgkin's granuloma showed a definite anergy to both types of tuberculin. The significance of this anergy is entirely obscure, but it suggests that tuberculosis is not the cause of Hodgkin's granuloma; furthermore, if an untreated case of proved Hodgkin's granuloma reacts positively to high dilutions of tuberculin, this indicates that the patient also has active tuberculosis.

In considering all the evidence at hand from reports in the literature and from our own work, we

are forced to conclude that the etiology of Hodgkin's granuloma has yet to be discovered.

INCIDENCE

Hodgkin's granuloma is, fortunately, an uncommon disease. Uddstromer⁵³ found only 548 cases in the whole of Sweden between 1915 and 1931, an incidence of 0.054 cases per 10,000 living persons as based on the average population of the country during that period. All cases were proved by biopsy or autopsy, and all tissue was examined by the author himself. Among 8485 general autopsies, Symmers⁵⁵ found 14 cases of Hodgkin's disease, and in Barron's⁵⁶ 7253 autopsies there were 24 cases. The combined incidence as estimated from these two latter series is 0.23 per cent. Ciechanowski⁵⁷ found an incidence of 0.33 per cent in 60,000 autopsies.

In our own series of 259 proved cases,* the total available figures must be broken down, for many cases were admitted to the Collis P. Huntington Memorial Hospital or the Pondville Hospital, two institutions that are devoted primarily to the care of patients with one or another form of malignant disease and likely, therefore, to have, in relation to the general population, a disproportionately large number of cases of Hodgkin's disease in their wards. A juster estimate of the incidence of the disease, so far as our own experience is concerned, may be derived from the figures at the Boston City Hospital.

TABLE 1. Age at Onset of Hodgkin's Paragranuloma.

AGE yr.	NO. OF CASES	PER CENT
0-9	2	5
10-19	6	16
20-29	9	24
30-39	6	16
40-49	4	10
50-59	4	10
60-69	6	16
70-79	1	3
Total	38	

At this institution, there were 16,773 autopsies from 1897 to 1943, and among these 35 showed Hodgkin's granuloma, an incidence closely approximating that of the combined figures of Symmers⁵⁵ and Barron⁵⁶ referred to above. It should be emphasized that all our autopsy and biopsy material of whatever date has been comprehensively reviewed by us personally during the last three years, so that in all cases the diagnosis has been made in the light of the most recent histologic knowledge.

We may tentatively conclude that Hodgkin's granuloma accounts for approximately 0.25 per cent of deaths in a general hospital.

Uddstromer⁵³ found the condition six times as common in 1931 as in 1915. He was hesitant in say-

*From the total number seen, only those cases were included from which we had at the time of study satisfactorily stained tissue and on which we had adequate clinical data, at least for the patient's first visit to the hospital.

ing that there had been an actual increased rate. Our data do not support the view that the disease is on the increase.

AGE AND SEX

Hodgkin's Paragranuloma

The age incidence of Hodgkin's paragranuloma is shown in Table 1; it roughly parallels that of the granulomatous form (see below). Of 38 patients, 27, or 71 per cent, were males.

Hodgkin's Granuloma

Although it has been repeatedly stated that Hodgkin's granuloma principally affects young adults, it is of the greatest importance to recognize that the condition may occur at any age. In the literature, there is no consensus concerning the decade in which it is most commonly seen, and some confusion has arisen from the facts that certain authors derive the age incidence from the date of the first symptoms, that others have recorded their cases according to the age at death, and that still others have contented themselves by saying that the disease "occurred in" certain decades.

Uddstromer,³³ who carefully dated his cases from the first symptom that could properly be attributed

to the disease, found that the condition was commonest in the third decade, but his figures (Table 2) indicate clearly that no age group is spared.

On the other hand, in Longcope's³² series of 109 cases, 19 per cent occurred in the first decade of life, and of Smith's³⁸ 138 cases, over 12 per cent were seen under the age of ten. In sharp contrast, Sternberg² reports 29 per cent of his autopsied cases as falling in the sixth decade and 25 per cent in the seventh, and Priesel and Winkelbauer⁵⁹ report a case of a child who apparently had the disease at birth and died at the age of four months. It is thus apparent from a study of the literature that no age is spared and that the condition is found with reasonable constancy throughout the first seven decades of life. Our own experience confirms this view, for our cases are distributed quite evenly from earliest childhood to the age of 70 (Table 3).

Wallhauser¹ believed that the number of cases developing during the period of puberty was sur-

prisingly and significantly small, since he found that of 33 cases in patients under fifteen, only 2 occurred between the ages of twelve and fourteen. Similarly, in Uddstromer's series of 57 cases with onset under the age of sixteen, only 6 came down with the disease "in the period of puberty," and of our own 43 patients under the age of sixteen, only

6, all boys, were first stricken between the ages of twelve and fourteen. As Uddstromer points out, however, the number of cases in the childhood period is so small that one must be cautious before drawing any broad conclusions on this particular point and, furthermore, the age at which puberty begins varies over rather wide limits in different latitudes and in various races.

For the present, the most important consideration is the undeniable fact that Hodgkin's granuloma may occur at any age, although it appears to be uncommon in infancy and in extreme old age.

There is general agreement that Hodgkin's granuloma is commoner in males than in females. Nearly 70 per cent of the patients in the 1447 cases collected from the literature by Wallhauser and 61 per cent of Uddstromer's 548 patients were males. This preponderance becomes even more marked in children, for 91 per cent of Uddstromer's and 94 per cent of Smith's patients under the age of ten were males. In our own series of 237 patients, 70 per cent were

males, and almost precisely this proportion was maintained in the childhood group. There does not appear to be any adequate explanation for this sex difference.

It is our belief that Hodgkin's granuloma occurs more frequently in members of the same family than can be accounted for by chance alone.

Hodgkin's Sarcoma

Hodgkin's sarcoma occurs chiefly in the middle-aged or elderly (Table 4). Eighty per cent of our 51 patients were over forty years of age. In no case have we seen a patient with primary Hodgkin's sarcoma—that is, not preceded by Hodgkin's granuloma—under twenty years of age. Twenty-six, or 51 per cent, of our patients were men. It is apparent, therefore, that both the age and the sex distribution differ sharply from those of Hodgkin's granuloma and paraganuloma.

SUMMARY

Hodgkin's disease, in our opinion, should be subdivided into the paraganulomatous, the granulomatous and the sarcomatous type. The nature, etiology and incidence of these three varieties have been discussed; their pathologic and clinical pictures and their treatment will be considered in subsequent articles.

THE DENTAL NEEDS OF MASSACHUSETTS CHILDREN OF TODAY*

PAUL E. BOYLE, D.M.D.,† WARREN R. SISSON, M.D.,† BASIL G. BIBBY, D.M.D.,§ AND
RUTH L. WHITE, B.S.¶

BOSTON

THE deplorable condition of the teeth of the young men of this country has been made prominent by the fact that dental defects have been the greatest single cause for rejection by the armed services. Massachusetts, in common with other New England states, has in this particular a record far worse than those of other sections of this country. That this regional record of relatively poor dental conditions is not a recent development is indicated by the fact that approximately the same rate of rejections for dental defects obtained in the Civil and Spanish-American wars and in World War I. In World War I, the rate for Massachusetts was 78.82 per 1000 men, whereas in Arkansas it was only 2.90 per 1000 men examined.¹ It might be thought that this great variation could be explained on the basis of different standards of dental examinations. This is probably not so, since the examinations were made at the camps by Army officers; furthermore, similar conditions were reported in the drafts of 1863 and 1864,² examinations made by Navy dentists agree closely with the figures reported from Army examinations³; and independent examinations of school children of ten to twelve years of age in Massachusetts and Maryland showed approximately twice as great an incidence of dental caries in the Massachusetts children.^{4,5}

The chief cause of loss of teeth in young adults is tooth decay. It might be assumed that this condition occurred to a similar degree in New England and in the rest of the United States, but that dental caries was less well treated and controlled here than elsewhere. A great deal of evidence indicates that such an assumption is not justifiable. For example, in a recent survey made by the Committee on Economics of the American Dental Association,⁶ it is stated that there is evidence of more adequate professional care in this section of the country than in any other. In addition, the proportion of dentists to the total population and the per capita amount spent for dental services are relatively high here. The conclusion is unavoidable that the incidence of tooth decay is actually higher here than elsewhere.

Tooth decay, once started, usually continues to destroy more and more of the tooth substance. Left untreated it almost inevitably leads to pulp abscess

and loss of the affected tooth. Detection of incipient caries by frequent inspections and x-ray examinations, removal of the diseased tooth structure and restoration of the normal tooth contours by means of fillings constitute accepted dental practice. Competent and continuous professional care can decrease the loss of permanent teeth in adolescents to practically zero. If such a program were started with every three-year-old child in the Commonwealth and carried through until the age of eighteen, there is little doubt that the major cause of loss of teeth, and hence of rejections for physical defects of a dental nature, would be eliminated. This program would be expensive and would require the training of additional personnel, but the returns in physical well-being and appearance and in freedom from pain would be of great value. Sweden⁷ and New Zealand⁸ have had experience with extensive programs designed to ensure a sound dentition for every child. The British⁹ and Canadian¹⁰ programs for compulsory health insurance, and the United States Social Security¹¹ program have been concerned with dental problems. The principle that the health of the individual is the concern not only of the individual himself, but of society as a whole seems destined to become the keynote of future public-health programs. The part that the dental profession may play in such a program is already a subject of study by the Massachusetts State Dental Society. Your committee recommends that the Massachusetts Central Health Council approve in principle the goal of adequate dental care for all children up to the age of eighteen.

The problem of providing dental care for boys approaching the draft age is an immediate one. There is no doubt that loss of teeth can be prevented by adequate dentistry. The provision of professional dental care is difficult at the present time when so many of the younger dentists are in service. The various dental organizations might well explore the possibility of more active co-operation with the Procurement and Assignment Service in its efforts to supply adequate professional service to all communities in the Commonwealth. Since even in peacetime it is estimated that approximately 70 per cent of the population receive no dental care other than treatment for the relief of pain, the magnitude of the problem under present conditions becomes apparent. The long period of training for the practice of dentistry makes it imperative that the time and skill of the dental operator be efficiently utilized. Relatively few dental practitioners

*A committee report read at the annual meeting of the Massachusetts Central Health Council, Boston, May 13, 1943.

§Dean, Tufts College Dental School.

¶Chief, Nutrition Department, Forsyth Dental Infirmary.

have studied the problem of attaining maximum productivity by the use of assistance, planned steps in operative procedure and the designing of equipment for efficiency rather than for show. The dental schools might well undertake to train students in time-saving methods of operating, since cumbersome procedures learned in school may persist as the habits of a lifetime. Dental schools might also assume responsibility for the training of dental assistants and laboratory technicians. The dental hygienist has already demonstrated her usefulness in dental practice and to some extent in school and hospital clinics. A much wider use of her services for dental examinations and possibly for simple operations, in addition to the cleaning of teeth, which is now permitted, might be considered. This would necessitate a longer period of training than at present, which would doubtless be advantageous in other respects.

Most of the dentistry for the people of Massachusetts is done by private practitioners. A significant part of the dental care for children is provided in the clinics of the Forsyth Dental Infirmary, the Harvard and Tufts dental schools and various smaller clinics, especially those maintained in primary and grammar schools. The latter are particularly handicapped at the present time because of the shortage of dentists. In general, recent graduates have served such clinics on a part-time basis while building up their private practices. It is chiefly these men who have gone into service, and no one is available to take their places. The immediate problem can be met only by using most efficiently the time of those who are left, a subject that has already been discussed.

Thought should be given, however, to the post-war program. It appears evident that adequate dental care can be made available to all the children of Massachusetts only by the use of public funds. This would provide dental care for all in the same way that a public-school education is provided without regard to the ability of the child's family to pay for such services. It would not eliminate private practice, just as private schools are not eliminated by the public schools. It would ensure adequate dental care for the total child population rather than for the minor part, as at present. This would necessitate creating opportunities in public-health dentistry that would appeal to young men and women as a career. Such positions should be under civil service and should offer security of position and opportunity for advancement as well as for service, in compensation for the greater financial rewards of private practice.

An important feature of such a program would be its continuity. Sporadic dental care may be completely ineffective in preventing loss of teeth. It is the opinion of the members of your committee that dental services should be available throughout the high-school period. To care for the teeth of children

through the primary-school and grammar-school years and then neglect them through four years when caries susceptibility is high is likely to make the work of previous years of little avail. It seems probable that such a program would benefit rather than harm private practitioners of dentistry, since it would inculcate habits of regular dental care up to the time when most persons become self-supporting.

At present the Massachusetts Department of Public Health has a dental unit consisting of two dentists and two dental hygienists. Despite the fact that Massachusetts was one of the first states to include dentistry in its public-health program, the appropriation for this purpose at the present time is less than 0.5 per cent of the total public-health budget, and this contrasts unfavorably with many other states. For example, in 1938, the proportion of the state budget allotted to dental-health programs was 3.1 per cent in Connecticut and 5.6 per cent in North Carolina.¹²

The members of your committee believe that the dental unit should eventually become a full division in the Department of Public Health. They recommend that the Commissioner of Public Health appoint an advisory council to this dental unit. This council might consist of representatives of the Massachusetts State Dental Society, the Oral Hygiene Council, the Forsyth Dental Infirmary, the Harvard School of Dental Medicine and the Tufts College Dental School. The advisory council could be of great assistance to the dental unit in planning a program to meet the dental needs of the people of Massachusetts.

So far we have been concerned with the problem of tooth decay and the steps that may be taken to arrest its progress and repair the damage it causes. What about the prevention of dental caries? Prevention is usually dependent on a knowledge of etiology, and the etiology of dental caries is unknown. Certain observations, however, appear to be well established: dental caries always starts on the outer surfaces of teeth; tooth structure is destroyed by the action of acids; a number of bacterial species found in the mouth are capable of producing acids; and sugars and starches constitute a favorable pabulum for these acidogenic bacteria. Whether these are primary or secondary causes cannot yet be decided. Such observations afford the rationale for attempts at preventing tooth decay by cleansing the teeth, and for the use of alkaline toothpastes and mouthwashes. The prevalence of tooth decay in spite of the expenditure of large sums on toothbrushes and dentifrices indicates that such measures are not effective.

Considerable evidence is available that sugars and starches promote the initiation and progress of tooth decay, and that the incidence of dental caries may be reduced by lessening the amount of these substances in the diet. It is quite possible that

wartime rationing of sugar and candies may lessen the amount of tooth decay in children.

A most important advance in the understanding of dental disease has come with the demonstration of the effect of nutrition on the development and maintenance of a healthy dentition. Good nutrition, especially during the developmental periods of the teeth, is generally recognized as a fundamental factor in dental health, although the mechanism by which this factor exerts its influence is a matter of dispute. Many investigators have reported a correlation between nutritional improvement and reduction of dental caries in children.

It is obvious that efforts to promote dental health through adequate nutrition should be correlated with, and indeed should be a part of, the more general nutritional program. Utilization of the present knowledge and equitable distribution of the available food supply would ensure better health, including better teeth. The fact should not be overlooked that teeth are digestive organs, and that normal mastication and salivary digestion cannot occur when the teeth are diseased or lacking. A well-selected diet may not be adequate if it is not properly digested, and the teeth play a part in the digestive process. Furthermore, it should be pointed out that eating habits are of importance in maintaining sound teeth. It is well established that such a simple procedure as finishing a meal with an orange or an apple rather than with cake or candy may be associated with relative freedom from tooth decay. This effect seems explainable chiefly on the local cleansing action of the fruit as opposed to the debris left on the teeth by the pastry, rather than to the superior nutritional value of the fruit.

The striking laboratory and clinical data now appearing in the literature concerning the effectiveness of small amounts of fluorine (less than 2 parts per million) in preventing tooth decay in human beings as well as in laboratory animals¹¹ have been considered by this committee. Although we are not ready to recommend the widespread use of this substance as a public-health measure, we believe that continued study of this phase of the problem should be made, and suggest that it might be used under proper supervision in some section of the

Commonwealth so that data may be obtained concerning its effectiveness in a region of the country where dental caries is most nearly universal.

A final word should be said concerning the responsibility of the medical profession for the control of dental disease. It is unfortunate that most physicians neglect to examine the mouths of their patients with the same care and attention paid to other parts of the body. The treatment of dental disease is the province of the dentist, but its recognition is equally the responsibility of the physician.

SUMMARY

Dental caries is a more serious problem in Massachusetts than in other sections of the country.

Early detection and treatment is an effective procedure, but it requires highly trained personnel and is therefore expensive. Ways of more efficient use of this personnel are suggested.

The promotion of a public-health dental service is discussed. The appointment of an advisory council to the dental unit of the Massachusetts Department of Public Health is recommended.

The etiology of dental caries is discussed, and the role of nutrition in controlling its ravages is commented on.

The responsibility of the medical profession for the recognition of dental disease is stressed.

PHENARSINE HYDROCHLORIDE IN THE TREATMENT OF SYPHILIS

WILLIAM P. BOARDMAN, M.D.,* AND ROBERT KALDECK, M.D.†

BOSTON

PHENARSINE hydrochloride is a mechanical mixture of 3-amino-4-hydroxy-phenyl-dichlorarsine hydrochloride with sodium citrate as a buffer diluent. Its chemical constitution and pharmacologic properties have been fully described by Long¹ and Guy, Goldmann and Gannon.²

The treatment of syphilis with phenarsine was begun in the Department for Diseases of the Skin of the Boston City Hospital one and a half years ago. The drug† was given in courses of ten to twenty injections, alternating with courses of fifteen injections of bismuth. The doses ranged from 0.030 to 0.045 gm. for women and from 0.030 to 0.067 gm. for men. In cases of primary and early secondary syphilis three injections a week were given for the first two or three weeks, and weekly injections after that to the end of the first course of arsenicals.

actions. One of these also had an eruption, and 1 developed jaundice and hypochromic anemia (Table 2). The treatment was changed to Mapharsen in 2 cases, to neoarsphenamine in 2, and to bismuth in 1, and 2 patients failed to report for further treatment. The patient who had jaundice and hypochromic anemia was a thirty-four-year-old Negress with primary seropositive syphilis and a positive dark-field examination. She developed jaundice and tenderness over the liver after having received seven injections (300 mg.) of phenarsine within two and a half weeks. The blood at that time showed a hemoglobin of 63 per cent, 3,360,000 red cells and 5800 white cells, with 71 per cent polymorphonuclear neutrophils, 2 per cent eosinophils, 1 per cent basophils, 20 per cent small lymphocytes and 6 per cent monocytes; the platelet count was normal.

TABLE 1. Summary of Data.

	TYPE OF SYPHILIS			
	PRIMARY	SECONDARY	LATE	ALL TYPES
Number of patients	14	31	67	112
Dropped	7	24	34	65
Remained under treatment	7	7	33	47
Cases with reactions	5 (36%)	8 (26%)	12 (18%)	25 (22%)
Drug discontinued because of reactions	2 (14%)	2 (6%)	3 (4%)	7 (6%)
Reactions:				
Nausea, vomiting and diarrhea	3	5	11	19
Jaundice and anemia	1			1
Eruptions	1	3	1	5
Total injections of phenarsine	131	391	777	1299
Total dosage of phenarsine	10416 mg.	18013 mg.	32928 mg.	61357 mg.

In later courses it was administered at weekly intervals throughout the courses. Bismuth subsalicylate in peanut oil was used in weekly doses of 1 cc. (0.075 gm. of bismuth) for fifteen doses. Phenarsine and bismuth were never given simultaneously. Cases of late syphilis received a course of bismuth at the beginning of treatment. Pregnant women were treated with phenarsine only. It was given to 112 patients who made regular visits (Table 1). This group included 14 cases of primary, 31 cases of secondary and 67 cases of late syphilis (early and late latent, and tertiary). During the period mentioned 65 patients dropped out for various reasons; 58 were transferred to other clinics, chiefly because they were near their places of employment, and the remaining 7 could not be traced.

Five patients had to discontinue the phenarsine treatment because of severe gastrointestinal re-

Treatment was continued with bismuth and the patient's condition improved rapidly. Four months later the hemoglobin was 78 per cent, the red-cell count 4,000,000, and the white-cell count 4250, with 69 per cent polymorphonuclear neutrophils, 2 per cent eosinophils, 9 per cent monocytes and 20 per cent lymphocytes. The red cells were slightly hyperchromic but normal in size and shape and the platelet count was normal. Five months after the beginning of treatment, the serologic reaction became negative and remained so. The patient has continued treatment with bismuth for fifteen and a half months and is in excellent health.

Mild reactions, mostly headache, dizziness and nausea, occurred in a number of cases. Five (36 per cent) of the 14 cases of primary syphilis showed some type of reaction. Among these, in only 2 cases were the reactions severe enough to cause discontinuance of phenarsine. Of the 31 patients with secondary syphilis, 8 (26 per cent) had reactions, but only 2 had to discontinue treatment. Of the 67 patients with late syphilis, 12 (18 per cent) showed reactions, but only 3 had to discontinue treatment.

*Physician-in-chief, Department for Diseases of the Skin, Boston City Hospital

†Resident, Department for Diseases of the Skin, Boston City Hospital.

*Supplied as Clorarsen through the courtesy of E. R. Squibb and Sons, New Brunswick, New Jersey.

When reactions appeared, phenarsine was continued in smaller doses, with the addition of 10 cc. of 50 per cent glucose or 10 cc. of 10 per cent sodium thiosulfate, which benefited half the primary cases and about three fourths of the cases of secondary

lesions required 3.7 weeks. Disappearance of the rash in secondary syphilis required only 2.8 weeks. The average time required for all lesions in primary and secondary syphilis was therefore 3.14 weeks, or about twenty-two days.

TABLE 2. Cases Showing More than Mild Gastrointestinal Reactions.

CASE NO.	DIAGNOSIS	KIND OF REACTION	DOSE OF PHENARSINE mg.	SUBSEQUENT TREATMENT	REMARKS
1	Primary syphilis	Headache, nausea, vomiting and diarrhea	6200	Neocarphenamine	
2	Primary syphilis	Hepatitis, jaundice and hypochromic anemia	7300	Bismuth	Seronegative after 5 mo.
3	Secondary syphilis	Vomiting and diarrhea	20922	Maparsen	Seronegative after 5 wk
4	Secondary syphilis	Headache, nausea and dermatitis	6380		Treatment discontinued
5	Secondary syphilis	Dermatitis	12760		Treatment discontinued
6	Late congenital syphilis	Vomiting and diarrhea	5225	Maparsen	
7	Late latent syphilis	Vomiting and diarrhea	7292	Neocarphenamine	

and late syphilis. From these figures it can be seen that a higher percentage of reactions occurred in the early cases, which received three doses weekly for the first two weeks, than in the secondary or late cases. When the serologic reversals to negative are considered, however, the cases that had received this intensified treatment also showed later a higher incidence of reversals. No case of nitritoid crisis, renal damage, purpura, encephalitis, optic atrophy or permanent damage to the blood-forming organs occurred. The only case showing liver damage was

Serologic reversal (Table 3) occurred in 6 (86 per cent) of the 7 cases of primary syphilis, and in 6 (86 per cent) of the 7 cases of secondary syphilis. In the 33 cases of late syphilis, there were 3 reversals or 9 per cent. Therefore, in the 47 cases remaining under treatment there were reversals in 15 or 32 per cent.

In the cases of primary syphilis the average values of 14.3 injections of phenarsine (881 mg.) and 3.5 injections of bismuth over a period of 10.8 weeks were needed to accomplish reversal. For the group

TABLE 3. Cases Showing Serologic Reversal from Positive to Negative.

TYPE OF SYPHILIS	NO. OF INJECTIONS OF PHENARSINE	TOTAL DOSE OF PHENARSINE mg.	NO. OF INJECTIONS OF BISMUTH	TIME REQUIRED FOR REVERSAL	REACTIONS
Primary	6.0	270	16	4½ mo.	Nausea
	10.0	499	0	2 mo.	None
	10.0	616	5	2 mo.	None
	14	872	0	2½ mo.	None
	36	390	0	3½ mo.	Erythema of Milian
	10	360	0	1 mo.	None
Secondary	12.0	525	13	4½ mo.	Nausea
	12.0	540	15	5½ mo.	None
	18.0	810	10	5 mo.	Vomiting and diarrhea
	6.0	270	0	½ mo.	Vomiting and diarrhea
	4.0	180	5	4 mo.	Vomiting and diarrhea
	31.0	876	30	3 mo.	None
Late	10.0	420	30	10 mo.	None
	10.0	516	16	9 mo.	None
	10.0	633	15	6 mo.	None
Averages:					
Primary syphilis	14.3	881	3.5	10.8 wk.	
Secondary syphilis	13.8	567	12.2	15.2 wk.	
Late syphilis	10.0	523	20.3	33.3 wk.	
General average	12.7	657	12.0	19.8 wk.	

the primary case previously described. No serologic relapses were observed in the cases under treatment. In the cases of primary and secondary syphilis, the exact time required for healing of the lesions was recorded in only 7 cases. The healing of primary

with secondary syphilis the figures were 13.8 injections of phenarsine (567 mg.) and 12.2 injections of bismuth over a period of 15.2 weeks. The 3 cases of late syphilis received 10.0 injections of phenarsine (523 mg.) and 20.3 injections of bismuth over a

period of 33.3 weeks. The average figures in all the cases with reversals were therefore 12.7 injections of phenarsine (657 mg.) and 12.0 injections of bismuth over a period of 19.8 weeks. It is of interest that the only case of primary syphilis under treatment that did not become negative had received only twelve injections of phenarsine (495 mg.) and no bismuth over a period of eight weeks — in other words, less than the average treatment received by the other 6 patients. This patient still has a good chance to become seronegative, which would raise the total number of reversals in this group to 100 per cent. The same applies to the only remaining patient with secondary syphilis, who had received only seventeen injections of phenarsine (965 mg.) in twelve weeks of treatment. From Table 2 it can be seen that among the cases with serologic reversal there was a higher incidence of reactions than in others. Among 15 recorded cases, 6 had reactions such as nausea, vomiting and diarrhea. One patient with primary syphilis, a pregnant woman, developed erythema of Milian on the ninth day of treatment. Treatment was continued, and on her request she received three injections of 67 mg. of phenarsine weekly. Within three and a half months she had received thirty-six injections of phenarsine (2390 mg.). No bismuth was given. By the end of this period the serologic reaction had become negative and she delivered a healthy child. After this she was treated with weekly injections of bismuth and the serologic reaction remained negative.

Whereas the incidence of reactions in all cases of primary syphilis was 36 per cent, in those of secondary syphilis 26 per cent and in those of late syphilis 18 per cent, in cases with later serologic reversal the incidence was 40 per cent. Nevertheless, the

number of severe reactions was small, and only 1 case of jaundice with anemia occurred, with complete recovery.

With this low toxicity, phenarsine compares favorably with Mapharsen. So far as reversals are concerned, Gruhitz and Dixon³ state that cases of early syphilis treated continuously with Mapharsen and heavy metals show reversal to negative in 88 per cent after six months of treatment, and in 96 per cent after ten months of treatment. When it is considered that many of our patients have been treated a shorter time than this, our figures are certainly as favorable as those given for Mapharsen.

SUMMARY

In 112 cases of all stages of syphilis, phenarsine hydrochloride (Clorarsen) when given intensively caused a fairly high percentage of minor gastrointestinal symptoms, but in only 7 cases were these so severe that the treatment had to be stopped. There was only 1 case of liver damage and anemia, and this patient completely recovered. There was no mortality, and no other serious reactions occurred. There was no case of clinical or serologic relapse, and the percentage of serologic reversals from positive to negative was as high as that obtained with other arsenicals. We therefore believe that phenarsine is a safe drug, and our results appear to warrant further therapeutic investigation.

MEDICAL PROGRESS

THE DIFFERENTIAL DIAGNOSIS OF CHICKEN POX AND SMALLPOX

CONRAD WESSELHOEFT, M.D.*

BOSTON

EIGHTY years ago an acrimonious controversy raged over Europe as to whether chicken pox (varicella) and smallpox (variola) were or were not the same disease.^{1,2} Both were endemic and epidemic at that time. The severe cases of chicken pox and mild cases of smallpox contributed to the confusion. Later there came into vogue the erroneous notion that chicken pox never attacks adults.³ Only within the past half-century have the two diseases been clearly differentiated. Indeed, they are entirely different. The classic picture of each can be recognized at a glance. Both, however, are subject to such wide variation that almost every point of differentiation may have an exception under certain circumstances. The importance of these points and their exceptions, particularly to military medicine, prompts this review.

EPIDEMIOLOGIC CONSIDERATIONS

Chicken pox is endemic in New England the year around. Epidemics usually begin in the colder months of the year and subside as summer comes on. In the Northern Hemisphere smallpox also occurs more frequently in the winter months.⁴ It was formerly both endemic and epidemic in New England, but of late has become pretty well extinct except for rare isolated outbreaks in communities where vaccination has not been properly enforced. It should be kept in mind that smallpox continues in the St. Lawrence Valley and that people from that area sometimes bring the disease to New England. Before the war it seemed paradoxical that so many New Englanders were vaccinated before going to countries in Europe that were free of smallpox, yet never gave a thought to vaccination before an extended motor trip along the St. Lawrence River, or to some states in the northwest where vaccination was not yet compulsory and where smallpox continued to occur.[†] The severest types of smallpox are epidemic in North Africa, the Orient, India and Mexico, the milder forms occur in the West Indies, northern South America, South Africa and Canada. In recent years outbreaks in the United States and Great Britain have been of milder variety.⁵

IMMUNOLOGIC CONSIDERATIONS

An attack of either chicken pox or smallpox tends to confer a lasting immunity. Most people in New England have chicken pox in early childhood and thereby, with rare exceptions, remain immune

throughout life. A few people exhibit a strong natural immunity through childhood and contract the disease in later life. Occasionally a parent who has not had the disease in childhood contracts it in a severe form from a mild case in one of his children. It is therefore desirable to have chicken pox in childhood in order to establish an immunity. If for any reason it is advisable to ward off an attack, an intramuscular injection of 10 to 20 cc. of convalescent chicken-pox serum within five days of exposure is likely to be effective because the incubation period is thirteen to twenty days.⁶ This passive immunity, however, lasts only two weeks.

Since cowpox affords a cross immunity to smallpox, it is advisable that all persons be vaccinated in early childhood. Indeed, whenever the question of a diagnosis of smallpox arises, one of the first steps is to look for a vaccination scar. This, of course, is only circumstantial evidence, because one can have varioloid, which is a mild form of smallpox modified through vaccination.⁷ Another point is that the incubation period of smallpox is about twelve days. Thus, in the event of an exposure to smallpox a certain degree of protection can be achieved by immediate vaccination.⁸ If the subject has had a previously successful vaccination, the amount of antibody already there is increased by the repeat inoculation of cowpox virus.

Although the incubation period of smallpox averages twelve days, it varies from eight to twenty-one days. The severer the form, the shorter is the incubation period. Thus, in so-called "black" or purpuric smallpox (variola purpurica), in which the patient succumbs in the period of invasion, the incubation period is only eight days. In such a case, the appearance of petechiae is followed by hemorrhages and collapse; the patient becomes the color of a "dark prune" and dies before the vesicular stage gets under way. On the other hand, in alastrim, which is a mild form of the disease in unvaccinated persons, the incubation period may be twenty-one days. Alastrim is due either to a high resistance in the individual or to a low virulence of the virus.

PRODROMAL SYMPTOMS

In general it may be stated that prodromal symptoms are absent or slight in chicken pox and severe in smallpox. The fact is that since chicken pox usually occurs in childhood and is usually a mild affair, prodromes are rarely present. Occasionally a child has a high fever, vomiting and even a convulsion within a few hours of the time when the first chicken-pox lesions are noted. Again, there may

MEDICAL PROGRESS

THE DIFFERENTIAL DIAGNOSIS OF CHICKEN POX AND SMALLPOX

CONRAD WESSELHOEFF, M.D.*

BOSTON

EIGHTY years ago an acrimonious controversy raged over Europe as to whether chicken pox (varicella) and smallpox (variola) were or were not the same disease.^{1,2} Both were endemic and epidemic at that time. The severe cases of chicken pox and mild cases of smallpox contributed to the confusion. Later there came into vogue the erroneous notion that chicken pox never attacks adults.³ Only within the past half-century have the two diseases been clearly differentiated. Indeed, they are entirely different. The classic picture of each can be recognized at a glance. Both, however, are subject to such wide variation that almost every point of differentiation may have an exception under certain circumstances. The importance of these points and their exceptions, particularly to military medicine, prompts this review.

EPIDEMIOLOGIC CONSIDERATIONS

Chicken pox is endemic in New England the year around. Epidemics usually begin in the colder months of the year and subside as summer comes on. In the Northern Hemisphere smallpox also occurs more frequently in the winter months.⁴ It was formerly both endemic and epidemic in New England, but of late has become pretty well extinct except for rare isolated outbreaks in communities where vaccination has not been properly enforced. It should be kept in mind that smallpox continues in the St. Lawrence Valley and that people from that area sometimes bring the disease to New England. Before the war it seemed paradoxical that so many New Englanders were vaccinated before going to countries in Europe that were free of smallpox, yet never gave a thought to vaccination before an extended motor trip along the St. Lawrence River, or to some states in the northwest where vaccination was not yet compulsory and where smallpox continued to occur.⁵ The severest types of smallpox are epidemic in North Africa, the Orient, India and Mexico, the milder forms occur in the West Indies, northern South America, South Africa and Canada. In recent years outbreaks in the United States and Great Britain have been of milder variety.⁶

IMMUNOLOGIC CONSIDERATIONS

An attack of either chicken pox or smallpox tends to confer a lasting immunity. Most people in New England have chicken pox in early childhood and thereby, with rare exceptions, remain immune

throughout life. A few people exhibit a strong natural immunity through childhood and contract the disease in later life. Occasionally a parent who has not had the disease in childhood contracts it in a severe form from a mild case in one of his children. It is therefore desirable to have chicken pox in childhood in order to establish an immunity. If for any reason it is advisable to ward off an attack, an intramuscular injection of 10 to 20 cc. of convalescent chicken-pox serum within five days of exposure is likely to be effective because the incubation period is thirteen to twenty days.⁶ This passive immunity, however, lasts only two weeks.

Since cowpox affords a cross immunity to smallpox, it is advisable that all persons be vaccinated in early childhood. Indeed, whenever the question of a diagnosis of smallpox arises, one of the first steps is to look for a vaccination scar. This, of course, is only circumstantial evidence, because one can have varioloid, which is a mild form of smallpox modified through vaccination.⁷ Another point is that the incubation period of smallpox is about twelve days. Thus, in the event of an exposure to smallpox a certain degree of protection can be achieved by immediate vaccination.⁸ If the subject has had a previously successful vaccination, the amount of antibody already there is increased by the repeat inoculation of cowpox virus.

Although the incubation period of smallpox averages twelve days, it varies from eight to twenty-one days. The severer the form, the shorter is the incubation period. Thus, in so-called "black" or purpuric smallpox (variola purpurica), in which the patient succumbs in the period of invasion, the incubation period is only eight days. In such a case, the appearance of petechiae is followed by hemorrhages and collapse; the patient becomes the color of a "dark prune"⁹ and dies before the vesicular stage gets under way. On the other hand, in alastrim, which is a mild form of the disease in unvaccinated persons, the incubation period may be twenty-one days. Alastrim is due either to a high resistance in the individual or to a low virulence of the virus.

PRODROMAL SYMPTOMS

In general it may be stated that prodromal symptoms are absent or slight in chicken pox and more severe in smallpox. The fact is that smallpox reaches usually occurs in childhood and is a trouble. Itching affair, prodromes are rarely severe. Occasionally one child has a high fever, or in vulsion within a few days. Lesions are noted. Agitation on the first ch...

* do not require compulsory vaccination.

vulva or on the prepuce. Sometimes, when the patient's resistance is exceptionally low, there is bleb formation. The contents of the blebs is usually pinkish from extravasations of blood. In seriously undernourished or otherwise debilitated infants, this bleb formation with secondary infection may progress to actual gangrene.¹⁰

The course of chicken pox, then, is usually two or three days of fever accompanying the eruption of vesicles, which continues over a period of two to five days. The scabs may come off in a week, but often they cling to a tough central root for two weeks or even longer. During the scab stage the patient is up and about.

The protracted course of events in smallpox consists of the severe and prolonged prodromes, followed by a brief period of lowered temperature and relative comfort. The first signs of the eruption then appear, usually during the third or fourth day of the acute illness, but in some mild cases as late as the seventh day. In general, all the lesions can be said to come out together, and thus tend to be at the same stage. This statement needs qualification, in the first place, because the lesions frequently appear twenty-four hours earlier on the face than elsewhere; and in the second place because in a given area one may find lesions in different stages of development.¹¹ Thus, the statement that lesions in a given area tend to be at the same stage must be taken not as a reliable rule but merely in relation to the wider variation seen in chicken pox. The lesions begin as macules that last twenty-four hours. After this there may be another twenty-four hours in which they have a shotty feel, but as has already been stated, this is by no means always present. Then come firm, walled, umbilicated vesicles that at the end of twenty-four to seventy-two hours become opaque pustules. A sensation of burning in the skin often accompanies this eruption. The fever, which has been slowly mounting through the vesicular stage, rises abruptly with the pustular stage. The pustules remain for four to six days and then turn into crusts and scabs. These often remain a week or two, and as they come off they leave red pits that at the end of several months become white pitted scars. In the mildest forms of smallpox, however, there is often no scarring.

The distribution of the lesions tends to be centrifugal, and they are especially numerous on the face and forearms and below the knees. In these areas they tend to become confluent and all are much the same size. This confluence of the lesions brings about another feature of smallpox — namely, edema. The swelling along with the eruption may distort the face beyond recognition. The eyelids are so swollen that they do not open. The wrists, forearms, ankles, palms and soles may also be so swollen as to cause actual pain in conjunction with the burning sensation in the pustules.

The smallpox lesions also attack certain mucous

membranes, as is the case in chicken pox, but they do so more extensively. Instead of a few spots on the palate there may be numerous lesions there as well as on the buccal mucous membrane and tongue and over the posterior pharyngeal wall. Even the larynx may be involved. These lesions of the mouth and throat can be so painful that they make swallowing almost impossible. Furthermore, they give rise to a most repulsive halitosis. Lesions may also occur in the nose, on the palpebral conjunctivas and on the vulva.

Over any area where there is irritation of the skin surface, such as that from a hatband, collar, shoulder strap, waistband, belt or garter, the lesions are likely to show well demarcated confluence. Faller¹⁶ has gone at length into this selectivity of smallpox lesions for irritated parts of the skin. He draws attention to the fact that the lesions tend to be more marked about a scar and over bony prominences. He states that there are fewer lesions on a scalp that is protected by plenty of hair than on a bald area. He emphasizes the axilla, which is a favorite spot in chicken pox, but in which relatively fewer lesions are found in smallpox. This, he says, is particularly true of the apex of the axilla, which is so often involved in chicken pox but rarely in smallpox. He adds that, in general, smallpox tends to avoid the flexures of the skin more than does chicken pox. A readiness for lesions to appear where there is solar, thermal or mechanical irritation is present in both diseases but is more marked in smallpox. Gunn¹⁷ remarks that chicken pox shows a predilection for the sheltered parts of the body, such as the axillas and groins, whereas the converse is true of smallpox; and further, that chicken pox tends to avoid prominent parts and extensor surfaces. He also states that smallpox lesions are inclined to gather about "the sites of Mantoux and Schick tests where recent positive reactions have been obtained."

The blood count offers nothing reliable in the differential diagnosis — at any rate, not when it is needed — that is, at the onset of both diseases, in mild smallpox and severe chicken pox. Marked variations in the findings of the later stages have been recorded. In purpuric smallpox, white-cell blood counts of 16,000 to 46,200 have been recorded.⁹ The pustular stage of smallpox is accompanied by a marked leukocytosis. It is important to keep in mind that the streptococcus is the common secondary invader of the pustule, and that therefore a leukocytosis is to be expected. The streptococcus may also be a secondary invader in chicken pox, but an elevated leukocyte count cannot be depended on as a guide in this. I have seen a case of severe chicken pox in an adult with an overwhelming streptococcal pneumonia and blood stream infection in which the white-cell count was 8000, with only 68 per cent neutrophils. Holbrook²⁷ states that in chicken pox there is apparently a strong stimulus to lymphocytic activity with an increase in plasma

cells. Hoffmann²⁸ found 3 to 10 per cent eosinophils in the first three weeks of smallpox, rising to 15 to 20 per cent in the fourth and sixth weeks, whereas in chicken pox the percentage of eosinophils was normal at first, rising later to between 4 and 10 per cent. Gradwohl²⁹ states that the blood picture of chicken pox offers no information of value, but that that of smallpox is one of hyperleukocytosis with many irritation forms and plasma cells and a regenerative shift on the fourth day. It is doubtful whether this information would be of much diagnostic importance in a severe case of smallpox, and in the mild cases the leukocyte count is often not affected in any way.³

There are several laboratory tests for smallpox, but they can hardly be said to be practical when one is confronted with a case that is suspicious.

Sensitization test. This requires that a rabbit be sensitized to cowpox vaccine over a period of two weeks, after which the belly is shaved and the fluid from the suspected vesicle or pustule is inoculated intradermally. Material from smallpox gives a positive reaction in twenty-four to forty-eight hours, whereas that from chicken pox gives no reaction. The rabbit can be used again during the next eight months.

Flocculation test³⁰ and complement-fixation reaction^{31, 32} These tests also involve the use of hyperimmune rabbit serum. The latter is more sensitive than the former. Provided the serum is at hand, both tests can be read promptly. They are definitely specific, but the first is not reliable in the first week of smallpox.

Intradermal cowpox-virus test. Cowpox (vaccine) virus heated to 56°C. is injected intradermally. A positive reaction can be obtained in a case of smallpox if the disease is sufficiently advanced to give an allergic reaction. This test is of no value in a previously vaccinated person.

Paul test. A needle dipped in the contents of the suspected vesicle is used to scarify the cornea of a rabbit. In smallpox, minute vesicles appear in forty-eight hours and ulceration follows; material from chicken pox causes no lesions.

Chick-membrane test.³³ Inoculation of the chorioallantoic membrane of a chick embryo with fluid from a smallpox vesicle gives a characteristic recognizable pox within forty-eight to seventy-two hours; no reaction occurs from chicken pox.

There is one situation that is exceedingly rare but that is worthy of mention — namely, concurrent chicken pox and smallpox. Schamberg¹⁸ reports such a case. More recently O'Connor³⁴ has described a case in which smallpox began six days after chicken pox.

* * *

There is no single feature, aside from specific laboratory tests, that can be relied on under all conditions to differentiate chicken pox and smallpox. The complete picture must be carefully studied. The patient, with the arms raised above the head, must be looked over from scalp to sole. Then the lesions must be closely examined. The rate and the manner of maturation of the lesions must be taken into consideration. Laidlaw³⁵ has pointed out the importance of realizing how mild smallpox can be. Wanklyn³⁶ has warned of the danger of relying too much on the presence or absence of "umbilication, shottiness, palatal and buccal lesions, lesions on the sole of the foot, cropping and uniloculation." Schamberg¹ has drawn

attention to the fact that in chicken pox one may find one or more lesions resembling smallpox, and vice versa. Ronaldson and Kelleher¹⁰ have described the anomalous forms of chicken pox. Hill¹⁹ has depicted the variety of lesions that are occasionally visible during each stage of the smallpox eruption. Finally, Faller¹⁶ and Gunn¹⁷ have reviewed the peculiarities of distribution of the lesions in the two diseases, as well as their behavior under the influence of previous irritation of the skin.

CASE 30011

PRESENTATION OF CASE

First admission. A thirty-two-year-old housewife entered the hospital because of epigastric pain.

The patient had been in apparent good health until about fifteen months before admission, four months after a normal delivery, when she developed severe midepigastric pain. The pain was gnawing, intermittent, lasted two or three days and was not related to or altered by the ingestion of food or soda or by bowel movements. It persisted. Four months before entry the pain became severer and more constant. It at first occurred either a week before or a week after the menses but later had no relation to them. She was seen in the Out Patient Department about one month prior to entry and a cervical dilatation was performed, without benefit. The pain became much worse, radiating around the left side to the middle of the back and being aggravated by motion. She was unable to sleep. There was no nausea or vomiting, but her appetite was poor. She had tarry stools and dysuria for several days early in the illness but had had no recurrence of these. There was a weight loss of 10 pounds during this period. The menses had always been regular, each period lasting five days.

Physical examination showed a poorly nourished "wasted," pale woman looking older than her stated age. The heart and lungs were normal. There were marked tenderness and voluntary spasm in the midepigastrium, and slight tenderness in the suprapubic region, without spasm. Some costovertebral angle tenderness was elicited on both sides. Pelvic examination showed a lacerated, eroded, tender cervix; there was considerable odorless creamy discharge. The uterus was of normal size but extremely tender. The left ovary was not palpated. The right was not remarkable.

The blood pressure was 90 systolic, 60 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,700,000, with 60 per cent hemoglobin. The white-cell count was 11,400, with 45 per cent neu-

trophils, 47 per cent lymphocytes, 5 per cent basophils and 3 per cent monocytes. The urine was negative. A blood Hinton test was negative. The nonprotein nitrogen was 16 mg. per 100 cc. The blood protein was 6 gm. per 100 cc., the chloride 91.5 milliequiv. per liter, and the sodium 137 milliequiv. per liter. Repeated stool examinations were guaiac positive. No stool culture was reported.

A gastrointestinal series was negative, as was a barium enema. A small-bowel enema through the Rehfuß tube showed slightly slow passage of the fluid filling the jejunum and the greater portion of the ileum. There was a delay in the passage of fluid at the junction of the middle and lower thirds of the right ileum on the right side of the abdomen. There was slight ballooning, for which no anatomical basis could be demonstrated. The barium entered the cecum at the end of thirty minutes, and half an hour later, the ileum, cecum and colon were filled with barium. No localized areas of narrowing or any other defects were seen. Proctoscopic examinations were negative but seemed to reproduce the pain. The temperature occasionally rose to 100°F., but the pulse and respirations were normal. A pre-operative diagnosis of endometriosis was made, and a hysterectomy and appendectomy were performed. Exploration of the entire abdomen and gastrointestinal tract was said to have shown no abnormalities. The spleen was twice the normal size.

Except for an occasional rise of temperature to 99.8 or 100°F. the postoperative course was uneventful. The epigastric pain had completely disappeared. Pathological examination of the uterus and the appendix showed no abnormality. It was deemed advisable to transfer the patient to the Medical Service for further study and determination of the cause of the positive guaiac test on the stool, but she refused and was discharged on the twenty-eighth hospital day.

Second admission (nine months later). After discharge the patient remained free from pain for about a month. She then noted a gradual return of symptoms, with the development of constant upper abdominal pain that occasionally radiated to the left thigh. On one occasion she had a severe attack of pain accompanied by chills and a bout of vomiting. The nature of the vomitus was not known. Her appetite became poor. There had been urinary incontinence and dyspareunia since operation. She had lost 19 pounds of weight.

Physical examination showed an emaciated, rather anxious woman complaining of mild abdominal pain. The heart and lungs were normal. The abdomen was tense, with mild generalized tenderness more marked in the upper half. The liver was palpated two fingerbreadths below the costal margin. There was questionable costovertebral-angle tenderness bilaterally. Pelvic examination showed tenderness throughout. There was marked generalized muscle wasting of the extremities.

*On leave of absence.

The blood pressure was 95 systolic, 70 diastolic. The temperature was 99.8°F., the pulse 90, and the respirations 20.

Examination of the blood showed a red-cell count of 5,000,000, with 12.5 gm. of hemoglobin. The white-cell count was 7200, with 80 per cent neutrophils. The platelets were normal. The neutrophils showed a shift to the left. The urine was negative. The stools were guaiac positive. A cephalin flocculation test was ++++ in twenty-four hours and ++++ in forty-eight hours. A van den Bergh test was negative. The blood protein was 6 gm. per 100 cc. A bromsulfalein test was negative. X-ray films of the chest were negative. The spleen did not appear enlarged. An intravenous pyelogram was negative. A Graham test showed a normally functioning gall bladder; many minute radiolucent shadows, with a dense ring about them, were present within the shadow of the gall bladder, which had the appearance of calculi. X-ray examination of the gastrointestinal tract was handicapped because of the refusal of the patient to take more barium. There was a questionable thickening of the gastric mucosal rugae, but no ulceration or narrowing could be seen. Considerable pylorospasm was noted, but the duodenal cap, the second and third portions of the duodenum and the upper jejunum filled normally. There was pressure on one of the loops of jejunum by a mass arising out of the pelvis, which might have been the distended bladder. The bones were normal.

The patient continued to complain of epigastric and considerable back pain. She was placed on a high-calorie, high-vitamin diet but was unable to take much food by mouth "because it was not Portuguese style." During the third hospital week she had several attacks of severe epigastric pain radiating through to the back. The temperature ranged between 100 and 100.5°F.; the pulse and respirations were normal. Her condition improved but slightly during the fourth week, and she was discharged home on a high-calorie, low-fat, high-vitamin diet, to return at a later date for cholecystectomy.

Third admission (one month later). Following discharge the patient continued to have severe epigastric pain and nausea but no vomiting. Her appetite remained poor. There was some additional weight loss.

Physical examination showed a markedly emaciated woman in acute distress. There were tenderness in the right upper quadrant, voluntary abdominal spasm and slight right costovertebral-angle tenderness.

The blood pressure was 90 systolic, 60 diastolic. The temperature was 100°F., the pulse 100, and the respirations 20.

Examination of the blood showed a red-cell count of 4,100,000, with 60 per cent hemoglobin. The white-cell count was 10,400, with 70 per cent neutro-

phils; the smear showed a shift to the left, with many band forms. The urine was negative. The stools were guaiac positive.

The patient was given several transfusions and intravenous injections of fluid, with chills and fever following each transfusion. Proctoscopy was again negative. The temperature during the first two weeks ranged about 100°F. On the fourteenth day the temperature rose to 104°F., and the pulse to 150; the respirations were normal. Examination showed diffuse tenderness with spasm in the right upper quadrant. Sigmoidoscopy two days later was negative.

On the eighteenth hospital day the patient developed marked abdominal distention, vomiting and diarrhea. The temperature ranged between 100 and 104°F. Examination showed marked abdominal distention with tympany. There was diffuse tenderness without any rebound. High-pitched peristalsis of an obstructive character was audible, with periods of hyperactivity and silence. There was pain in both shoulders. X-ray films showed several loops of small bowel that were distended with gas, but no free air was seen in the peritoneal cavity. The white-cell count was 15,800. The urine showed a + test for albumin, and the sediment contained many white cells. A Miller-Abbott tube was passed but could not be manipulated beyond the pylorus.

On the twentieth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. J. H. MEANS: This is a case of some complexity, and of extraordinary interest as a problem—a tough problem, it seems to me—in differential diagnosis. The outstanding feature is that this syndrome was characterized by extremely persistent and at times apparently severe midepigastric pain that was peculiar in its lack of relation to any other bodily function and by gradually increasing fever and weight loss. The only clue that has been given concerning its nature is that it was reproduced by doing a proctoscopy. Whether that is of importance I do not know; but it did interest me. This affair had been progressing for two years and was relieved by hysterectomy but for only a month. It is interesting that the pathologist apparently found the uterus to be normal. The appendix was taken out at that time, so that is out of the picture, and finally the story ends with an attack of acute intestinal obstruction that required an emergency operation. It does not sound like a long-planned operation. I suppose it led to a diagnosis.

This case was thoroughly studied, and there is a great deal of material here for digestion. I made a list of positive findings, and there also are a great many significant negative ones. The pain itself I put first. I am much impressed with the one attack of tarry stools and the fact that every stool thereafter was guaiac positive. We cannot escape that.

She had been constantly losing blood in the stool. She had progressive weight loss, emaciation and hypochromic anemia. I shall ask the radiologist to interpret the films later, but it appears that the radiologist found some evidence of stasis, at least in the small bowel. There was questionable enlargement of the liver. The patient apparently had gallstones. The positive cephalin flocculation test might go with an enlarged liver, suggesting some parenchymatous disturbance in the liver or disturbance in liver function. In looking the record over very thoroughly, it seems to me that we have to find a focal lesion somewhere as an explanation for the picture, and I think it is reasonable to assume that it was below the diaphragm.

The case in favor of the gastrointestinal tract as the location is the strongest, and yet there are some things that bother me about attributing it to the gastrointestinal tract. There is this business about the pelvis. I am disturbed about the backache, which could be due to the gastrointestinal lesion. One can have backache in peptic ulcer, so that the backache could be of alimentary origin. There was pain in various places, — in the upper quadrant, in the suprapubic region and once in the left hip, — although usually it was in the midepigastrium. It was a bizarre type of pain.

I thought of disease in the kidneys, but there was a negative pyelogram and the urine was negative until just before operation, when it had some pus in it as a part of the acute picture. I thought about the pancreas, but I cannot explain all the picture on the basis of a pancreatic lesion. Nor can I explain it all on the basis of the gall bladder. She could have had liver disease. The liver is said to have been enlarged, but that is questionable. The cephalin flocculation test was suggestive of some disturbance in liver function, but the other tests were negative. The liver I shall leave on the periphery, as a possible but not probable locus of the lesion.

I thought of spinal disease, psoas abscess and things of that sort and abandoned them all, and came back to the gastrointestinal tract as the probable location of the lesion. The gastrointestinal tract was thoroughly studied. Everything was negative except the small bowel, so I was forced to conclude that the lesion was in the small bowel, although small-bowel lesions other than duodenal are rarer than those of the large bowel or stomach. At this point I shall ask the radiologist to give what help he can.

DR. MILFORD SCHULZ: Most of these films are just confirmatory of all these negative examinations.

DR. MEANS: Is there anything wrong with the spine, such as metastatic disease?

DR. SCHULZ: There is no gross lesion in the bones.

These are the films that we made at the time of the examination of the small bowel. The delay in the passage of barium through the small bowel was

a fluoroscopic observation. The small-bowel pattern is not unusual, and there does not seem to be a mass displacing it. Of course it is notorious that lesions in the small bowel are overlooked, or not demonstrated in x-ray examinations. Meckel's diverticulum and things like that are rarely found.

This is the film made on the second admission. The mass could well be a full bladder. On the other hand the bowel is not entirely filled and it is impossible to say whether or not an abdominal mass is present. The rest of the films are confirmatory of what has been said.

DR. MEANS: You cannot tell me with confidence that there is obstruction in the small bowel?

DR. SCHULZ: There is no obstruction. The barium enters the colon without any evidence of dilatation of the small bowel. The small bowel pattern itself seems to be normal.

DR. MEANS: Can you say that there was stasis in the small bowel that was pathologic?

DR. SCHULZ: Not from these films. That probably was the observation of the man who did the fluoroscopy and administered the small-bowel enema.

DR. MEANS: I have to go on what evidence I can get. Do you think I can assume that the fluoroscopist's opinion that there was delay in the small bowel is something to be taken seriously?

DR. SCHULZ: I do not know what to make of the impression of hesitancy in the passage of barium in the small bowel. I am willing to grant that it was a reliable observation.

DR. WILLIAM B. BREED: Does not one of these pictures show dilatation of the small bowel?

DR. SCHULZ: Yes; but the film was taken just before surgery and shows obstructed small bowel, distended with gas.

DR. MEANS: The patient had intestinal obstruction by that time. Can you locate it? Was it in the small bowel or large bowel?

DR. SCHULZ: I suspect that it was in the small bowel. The loops that you see here are jejunal. There may be a small amount of air in the colon, but the colon is not correspondingly dilated.

DR. MEANS: It seems to me quite evident that the patient had intestinal obstruction at the end. Why did she have it? Of course I could go through all the causes of acute intestinal obstruction. There is no need to do that, however, and I shall consider only those things that fit with the rest of the total picture. When the surgeons performed the hysterectomy, they carefully explored the abdomen and found nothing pathologic. Furthermore, a gastrointestinal series, special small-bowel films, barium enemas, pyelograms and cholecystograms, all were negative, except that gallstones were found.

Regarding differential diagnosis, first of all there is this matter of endometriosis. I bring that up because it was brought up by the service. I gather that the diagnosis was never confirmed. Could it be endometriosis? I do not know a great deal about

this disease but the textbooks state that it may involve the bowel, rarely the small bowel. Indeed it occasionally gives rise to bleeding of the small bowel, although the lesion generally does not extend through to the mucosa. So I think that endometriosis of the small bowel is extremely unlikely.

I thought of regional ileitis, of course, because it is a disease of the small bowel and I had rather sold myself the idea that the trouble was in the small bowel. Regional ileitis I rule out because the radiologist found no evidence of characteristic sort, and because the patient did not have, according to my interpretation, recurring attacks of incomplete obstruction, which are usually found in regional ileitis.

I thought of tuberculosis of the bowel. It can occur in the small bowel, but it usually involves the cecum as well, shows on x-ray study, and is usually secondary to tuberculosis elsewhere. I shall dismiss it.

A case of a peptic ulcer in a Meckel's diverticulum was presented here some time ago; that intrigued me a little bit. Such lesions do bleed. They are peptic ulcerations — apparently a Meckel's diverticulum often contains some gastric mucosa, which may produce a peptic ulcer. This patient's pain was high, whereas I should expect it to be around the umbilicus in a lesion of Meckel's diverticulum; but we cannot have everything just as we want it in these conferences. Therefore, I think that a peptic ulcer in a Meckel's diverticulum should be kept as a possibility. We have to find some lesion that explains the back pain and persistent bleeding. Those seem to be the things that are crying more for explanation than anything else. These two symptoms seem to be the salient features. A lesion in the small bowel that was bleeding persistently would result in anemia and interference with nutrition, so that the patient developed a progressive wasting disease. I suppose peptic ulcer of a Meckel's diverticulum could do these things. It does occur in adults but is commoner in children.

The matter of cirrhosis has to be mentioned. I do not know whether or not the liver was enlarged. The abdomen had been looked into, and seemed to be perfectly normal. I do not believe that she had cirrhosis, but it has to be mentioned in the differential diagnosis because it could have given rise to gastrointestinal bleeding. But the bleeding was different in character than what one gets in cirrhosis. It is not apt to be a steady oozing, as it was in this case. She had one bout of massive bleeding in the beginning, to be sure, but generally it was steady oozing, which is not characteristic of cirrhosis. The positive cephalin flocculation test indicates that perhaps the liver was "sick." No varices were demonstrated by x-ray, but the radiologist does not always disclose varices. Another source of varices is splenic-vein thrombosis, but I cannot square this picture with that condition. Cirrhosis should be mentioned but is unlikely.

I suppose that the gallstones could have produced the pain, although it certainly was far from typical. I do not see how gallstones could have produced the bleeding, therefore I conclude that they had nothing to do with the picture.

Next, one has to think of all the tumors of the small bowel that might ulcerate within the lumen and cause such a picture as this. There are the benign ones — fibromas, myomas, angiomas and lipomas. Then there is carcinoma, and finally lymphoma. At this point I ran out of ideas. I shall limit my differential diagnosis to the conditions mentioned. Perhaps the joker will be that the lesion was not in the small bowel. What was this thing in the pelvis? Was it bladder? It was not uterus. I do not know what it was. The pelvic examination, as I remember it, was negative.

Of all these various things that I thought of, I believe that lymphoma is the most probable. I think that it could do everything that is present in this case. It even could cause this backache. There might be retroperitoneal involvement by a lymphomatous process that no one could demonstrate. Costovertebral tenderness could have been due to involvement of the kidneys. I know that lymphoma can involve the small bowel, giving a localized tumor that often ulcerates and bleeds. It can also cause acute intestinal obstruction. Therefore I shall put lymphoma first. I think that the other things that I mentioned are possibilities. I should like to ask the pathologist whether lymphoma ever involves the adrenal glands and produces the picture of Addison's disease.

DR. BENJAMIN CASTLEMAN: It may involve the adrenal glands when the lymphoma is generalized. I have never seen it limited to the adrenal glands or produce the symptoms of Addison's disease.

DR. MEANS: I was intrigued by the low blood pressure, but I do not believe that it is important. There is no mention of pigmentation, and the gastrointestinal picture was not that seen in Addison's disease. There was a low blood chloride, but a normal blood sodium. I mention it but I do not believe that the patient had Addison's disease.

DR. BREED: I recall your discussing the case of a patient who had a hole in the diaphragm. This picture is certainly characteristic of a diaphragmatic hernia, and with the usual epigastric pain and bleeding, I wonder whether the x-ray man missed it and whether the exploring surgeon missed it. I just toss it in as a thought.

DR. MEANS: It is an interesting suggestion and had not occurred to me. I assume that they ruled out all these things because they look routinely for diaphragmatic hernia, certainly in cases of obscure pain. Diaphragmatic hernia certainly gives rise to pain and to bleeding. It might be considered. The way I interpret this picture, however, is that they found nothing at laparotomy, because at the time the lesion was within the lumen.

DR. CASTLEMAN: Would you not see something in the film of the chest if it were a diaphragmatic hernia?

DR. MEANS: The case that Dr. Breed refers to was interpreted roentgenologically as hydropneumothorax, which it was not. It was a stomach that filled the entire chest and was half filled with fluid.

A PHYSICIAN: How about partial intussusception that released itself and just gave enough symptoms?

DR. MEANS: I thought of intussusception as a possibility, but did not go into the actual nature of the acute intestinal obstruction just before the last operation. Any lesion within the lumen of the small bowel may set up intussusception and cause obstruction, I suppose. I am sure that the whole story, from start to finish, is not that of intussusception.

DR. REED HARWOOD: Did the mass in the pelvis, thought to be a full bladder, persist, or did it disappear?

DR. A. G. BRENIZER: The mass was not palpated on physical examination until the last entry. It felt as if it might be loops of bowel matted together, but it was not definite and was not included in the record for that reason.

DR. FLETCHER H. COLBY: How about mesenteric thrombosis? It would account for the last episode.

DR. MEANS: I was working harder on the two-year story than on just what happened before laparotomy. Mesenteric thrombosis may have occurred, but I do not see how it would hook up with the two-year story.

DR. CASTLEMAN: Dr. McKittrick, will you tell us about your operative findings?

DR. LELAND S. MCKITTRICK: It is too bad we did not have Dr. Means on the service. We are not proud of our diagnosis.

The patient had gallstones, but everybody thought that they could not conceivably give the picture that she had and we transferred her to the Medical Service for complete study. The mass in the lower abdomen did not disappear after the bladder was catheterized. We were disturbed about the persistently positive guaiac tests on the stools. We thought that the lesion was in the small bowel. We did not give quite the careful consideration in differential diagnosis that Dr. Means has, so we did not do well. We thought that the diagnosis lay between tuberculous peritonitis, with involvement of the bowel, and a regional enteritis. An operation was performed on that basis, and also with the assumption that recent perforation had occurred, with abscess formation. She had a large perforation and a walled-off abscess containing 50 to 60 cc. of small-bowel contents. We removed a segment of friable, open, small bowel and did an anastomosis, without knowing at the time what the lesion was. One of the members of the Pathology Department looked at the specimen, but even then it was difficult to be sure just what the lesion was; that is where we left it.

CLINICAL DIAGNOSIS

Tuberculosis of small intestine, with tuberculous peritonitis?
Regional enteritis?

DR. MEANS'S DIAGNOSES

Lymphoma of small intestine.
Acute intestinal obstruction.

ANATOMICAL DIAGNOSIS

Malignant lymphoma, lymphoblastic type, of small intestine, with perforation.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The fresh specimen contained many matted loops of hemorrhagic small bowel covered with a fibrinous exudate. When these were opened we were able to find a stenotic lesion about 3 cm. long in about the midportion of the specimen. The tumor was submucosal. Microscopic examination confirmed Dr. Means's diagnosis of lymphoma of the small bowel, which had perforated. We classified it as a lymphoblastic type of lymphoma. The regional lymph nodes, as is usual in isolated lymphoma of the gastrointestinal tract, showed no evidence of disease.

The patient is now convalescing.

CASE 30012

PRESENTATION OF CASE

A sixty-year-old man, a schoolteacher, was admitted to the hospital because of increasing dyspnea and peripheral edema of several weeks' duration.

Fourteen years before entry the patient noted shortness of breath and rapid heart action. He consulted a physician and was found to have auricular fibrillation. He was given digitalis, which he took regularly thereafter. Ten years before entry he stopped taking the drug for a brief interval, but returned to it because of the reappearance of dyspnea. Throughout the fourteen years he carefully regulated his existence. Two years before entry he consulted a cardiologist because of dyspnea. He was given subcutaneous diuretics, and voided 6 to 8 liters of fluid, with much relief. On two subsequent occasions similar diuresis was employed. About a year before entry he began to require more pillows for sleeping, and shortness of breath troubled him in his work. Eight weeks before entry he had an attack of grippe characterized by slight fever, malaise and a cough which, though slight, produced small amounts of sputum tinged with bright-red blood. Following this, the legs, scrotum and abdomen became swollen, and shortness of breath in-

creased. There was marked oliguria without response to diuretics.

The remote history and family history were irrelevant.

Admission examination showed a well-developed man sitting up in bed with marked dyspnea. There was advanced edema of the legs, sacrum and back. The face and extremities showed a deep-purple cyanosis. The veins over the neck and extremities were distended. There was questionable dullness with moist rales over both pulmonary bases. The heart was much enlarged, extending 10.5 cm. to the left of the midline in the fifth interspace. A loud systolic murmur was heard at the apex, with a soft blowing diastolic murmur along the left sternal border and a questionable diastolic murmur in the mitral area. There was auricular fibrillation, with an apical rate of 93 and a radial rate of 78. The abdomen was edematous, with the liver edge five fingerbreadths below the costal margin. The blood pressure was 128 systolic, 100 diastolic.

Examination of the blood showed a red-cell count of 5,900,000, with 18.1 gm. hemoglobin, and a white-cell count of 12,200, with 83 per cent neutrophils. The nonprotein nitrogen was 42 mg. per 100 cc. The urine showed a +++ test for albumin and a specific gravity of 1.022; there were a few red and white cells in the sediment.

The patient was given diuretics, and Southey tubes were inserted. In the course of eleven days he lost 37 pounds of fluid. The drainage incision in the left foot became infected, and a cellulitis developed.

During the third week in the hospital the patient began to lose ground. He developed purpuric areas on the left foot and right hand, and became more and more cyanotic. The cellulitis of the dorsum of the left foot spread widely but did not extend past the lower leg. *Staphylococcus aureus* and a beta-hemolytic streptococcus were twice cultured from the foot. A blood culture was negative. Terminally, bronchial breathing appeared at the left base and the patient became mentally confused. He died on the thirty-fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. DERA KINSEY: Obviously this patient's immediate problem was marked congestive heart failure. From his history we know this congestive failure began fourteen years before entry and may have been precipitated by the onset of auricular fibrillation. The kind of heart disease the patient was suffering from is not so obvious because we have no record of the physical findings until the terminal illness, at which time there was marked cardiac enlargement with both right and left ventricular failure, as indicated by dyspnea, engorgement of the neck veins and liver, and edema of the lower extremities, sacrum and back.

It is impossible definitely to evaluate the murmurs

described in this completely failing heart, since all of them might have been due to dilated and distorted valvular rings secondary to dilatation and hypertrophy of the heart. If the questionable diastolic murmur was really heard in the mitral area, however, we must strongly suspect rheumatic heart disease with mitral stenosis. It is interesting to note that the admission blood pressure was 128 systolic, 100 diastolic. This high diastolic pressure suggests that the patient previously had had hypertension, although there is no past history of it or of angina. We should like to have had further studies, such as fundi examination, electrocardiograms, x-ray films and so forth. Nor was there a previous history of rheumatic fever. The patient might well have had both rheumatic heart disease, with mitral stenosis, and essential hypertension since these two conditions are not uncommonly found in the same patient. He probably did not have beriberi, thyrotoxicosis or congenital heart disease because of the long duration and the age and lack of history. The orthopnea and dyspnea that the patient experienced in the beginning of his illness might have been due to acute ventricular failure as a result of hypertension or pulmonary edema as the result of mitral stenosis and precipitated by the sudden onset of auricular fibrillation.

This patient got along fairly well with his carefully planned existence until he developed a complication. Most people with congestive heart failure die of a complication rather than of the congestive failure per se. The commonest complication in congestive failure is pulmonary infarction, and second, pulmonary infection. Often the two appear together. The onset of this patient's terminal illness was probably due to pulmonary embolism and infarction. We may suspect this because of the so-called "attack of grippe," which was characterized by fever, malaise and the blood-tinged sputum. We know that chest pain is not always present with infarction. Further evidence of infarction are the mild polycythemia and the elevated hemoglobin level, both of which are consistent with cor pulmonale, which is associated with pulmonary infarction. It is unusual to note cyanosis to the extent this patient had in congestive failure alone. Pulmonary infarction in congestive heart failure is usually due to an embolus from the leg vein. It may also come, however, from the right side of the heart in the presence of mitral stenosis. In this patient, there is no indication by physical findings to the source of the emboli. The infarction might also have been due to local pulmonary thrombosis. The albumin and increased nonprotein nitrogen might have been caused by circulatory failure or, still more likely, by vascular nephritis and circulatory failure. The patient no doubt had a terminal bronchopneumonia.

My diagnoses are hypertensive coronary heart disease, questionable rheumatic heart disease with

mitral stenosis, pulmonary infarction with terminal pulmonary infection, cor pulmonale and cellulitis of the foot.

CLINICAL DIAGNOSES

Rheumatic heart disease with mitral stenosis, slight aortic involvement (regurgitation) and tricuspid regurgitation (?).
Local infection and gangrene: left foot.
Congestive failure.
Auricular fibrillation.

DR. KINSEY'S DIAGNOSES

Hypertensive coronary heart disease.
Rheumatic heart disease, with mitral stenosis?
Pulmonary infarction, with terminal pulmonary infection.
Cor pulmonale.
Cellulitis of foot.

ANATOMICAL DIAGNOSES

Rheumatic heart disease.
Endocarditis, chronic rheumatic, with aortic and mitral stenosis.
Mural thrombi: right and left auricles.
Chronic pulmonary thrombosis (? embolic).
Pulmonary endarteritis.
Cor pulmonale.
Cirrhosis of liver, cardiac.
Hemorrhagic bronchopneumonia: right lower lobe.
Hydrothorax, slight, right.
Sepsis: left foot.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The post-mortem examination showed severe chronic rheumatic heart disease with mitral and aortic stenosis. The heart was markedly hypertrophied, weighing 700 gm. With severe mitral disease one expects some degree of hypertrophy of the right ventricle, but in this case the right wall measured 11 mm. in thickness, or almost four times the normal, so that some additional factor must have been superimposed on the mitral stenosis. The major branches of the right and left pulmonary arteries were almost completely occluded by adherent organized thrombi. The smaller branches showed atherosclerosis but no thrombi. Whether these thrombi originated as emboli and then increased in size by superimposed thrombosis is anyone's guess. I personally believe they began as emboli, which may have arisen from the right auricular appendage, which was filled with thrombus, or from the deep leg veins. Microscopically there was marked intimal atherosclerosis of the small arteries. There certainly was enough cutting down of the pulmonary circulation to produce the cor pulmonale. There were no infarcts, apparently because these thrombi or emboli were in the larger vessels and had developed slowly enough to allow for collateral circulation.

Other findings were hemorrhagic bronchopneumonia in the right lower lobe, cardiac cirrhosis of the liver and a mural thrombus in the left auricular appendage as well as in the right. The coronary arteries showed only slight sclerosis.

DYSENTERY

For many centuries, dysentery has been a serious problem in times of stress, such as famine and war.¹ Epidemics during World War I, particularly that during the campaign at Gallipoli, are well documented, and accounts of outbreaks during the German invasion of Poland in 1939² and in the more recent campaign in the Middle East³ demonstrate that this epidemic disease still stalks armies. More important, however, is the fact that troops of the United Nations are now fighting or stationed in notoriously bad endemic areas—West and North Africa, several islands in the South Pacific, India, the West Indies, and Central and South America.

The commonest types of dysentery are caused by

a variety of bacteria and by an ameba, *Endamoeba histolytica*, but bacillary dysentery is by far the more important and serious. Other diseases, such as schistosomiasis, kala-azar and malaria, can cause dysentery, but these types seldom assume epidemic proportions.

In a recent and important review of bacillary dysentery, Weil⁴ has pointed out the accumulation of a considerable amount of new information during the last fifteen years, much of which has not found its way into textbooks and into practical application in medicine and public health. This fact is regrettable because of the continued occurrence and relatively high incidence of this disease in many parts of the world and in certain areas of this country.

According to the *Public Health Reports*, the reported cases of dysentery in the United States in 1940 were as follows: amebic dysentery, 2991 cases; bacillary dysentery, 19,152 cases; and undetermined, 1484 cases. Although mortality figures are distorted because many cases are unreported, the mortality of 17.8 per cent among 79,042 reported cases of bacillary dysentery from 1933 to 1937 gives an idea of the importance of the problem in normal times in this country.⁵ The situation for Europe and Japan is somewhat similar, with comparable morbidity and mortality figures. Obviously these figures cannot be applied to tropical countries, where everyone faces the likelihood of infection.

In both types of dysentery, man is the source of organisms for the contamination of food and water. Cysts of *E. histolytica*, the infective stage of amebic dysentery, cannot withstand drying but they can remain viable in water from several days to approximately five or six months, depending on the temperature, the amount of bacterial growth and the concentration of suspended organic material.⁶ Dysentery bacilli can withstand drying for twenty to twenty-five days⁷ and can live for variable lengths of time in flies, ants, milk and water. Thus, healthy carriers of *E. histolytica*, chronic cases of amebic dysentery, and convalescent or contact carriers of dysentery bacilli are of the utmost significance to the public-health official and to the medical officer in the armed forces.

In New York City, studies of 6324 healthy per-

sons for dysentery bacilli gave an incidence of 2 per cent, and the figure rose to 3.2 per cent when 1659 persons were examined in New Mexico, Georgia and Puerto Rico.⁴ Hurst and Knott⁸ state that not less than 1 per cent of all patients with Flexner infections become permanent carriers. The incidence and persistence of infections in institutions where the disease is endemic can be as high as 80 per cent. In troops fighting in endemic areas, the problem is a serious one and campaigns can easily be disrupted because of the occurrence of an epidemic.

Among a civilian population, modern methods of sanitation effectively control epidemics of bacillary dysentery in normal times, but poor housing conditions, too rapid growth of towns and cities, and crowding of defense workers cause the best laid systems of sanitation to break down in times of war. The present war of rapid movement minimizes the dangers in an army to some extent, but the problem of supplying food and water in tropical areas is potentially a great source of danger.

A correct laboratory diagnosis is essential for the clinician to verify the disease that confronts him. Emphasis should be placed on the facts that dysenteric infections can assume a variety of forms and that not all dysentery is caused by amebas or bacilli. Only after a thorough search of the feces for pathogenic bacteria and protozoa, and a blood examination for malarial parasites if the patient comes from an endemic area, is the clinician in position to treat the case properly and to control the spread of infection. Under field conditions, this procedure is not only impractical but often impossible for medical officers, and the only available procedure is a therapeutic test—quinine or atabrine for malaria, carbarsone or yatren for amebic dysentery and sulfonamides for bacillary dysentery. Of the last, sulfathiazole and sulfaguanidine have been given the most extensive trials; however, after sulfathiazole, fecal samples may become positive again for dysentery bacilli, and sulfaguanidine appears to be more effective against the Flexner bacilli than in Sonne infections. From the many and varied recent reports on the treatment of bacillary dysentery, it is quite apparent that the trials have been too few to properly evaluate sulfonamide drugs. The opportunity provided by

the present emergency will at least provide numerous occasions to prove or disprove their efficacy.

CANCER REMEDIES

EVEN in the midst of war, purported cancer remedies continue to appear. The most recent flurry is concerned with an English preparation known as "H 11." This is an extract of urine that is supposed to have tumor-inhibiting properties. As usual, the earlier reports appeared promising but the later give little, if any, hope that the substance is of value.

The material, prepared by Thompson,^{1, 2} has been utilized by several groups for therapy of both human cancer and induced as well as spontaneous transplantable cancer in animals.^{3, 4} In one series of 51 advanced cases of cancer, 37 cases received dosages that might be regarded as sufficient for fair clinical trial.⁵ Among these, 11 died and the results were unknown in 5 cases. The longest period of survival was eighteen months. All the patients surviving, except two (who lacked biopsy proof of the presence of cancer) had some other form of therapy in addition to H 11. In none of the cases in which H 11 was used did the growth disappear. There was a suggestion of slight clinical improvement in some cases, but this has often proved to be misleading in evaluating remedies.

The evidence seems to indicate that this urinary extract is without value as a therapeutic agent in cancer.

MEDICAL EPONYM

PARDEE'S SIGN

Harold E. B. Pardee (b. 1886) describes "An Electrocardiographic Sign of the Coronary Artery Obstruction" in the *Archives of Internal Medicine* (26:244-257, 1920). A portion of the article follows:

... It is hoped to show that obstruction of a branch of coronary artery is followed by a sign which is characteristic of this condition and is readily recognizable in the human electrocardiogram.

... The characteristic changes appearing a day or two after the obstruction are as follows: The QRS group is usually notched in at least two leads, and usually shows left ventricular preponderance. The T wave does not start from the zero level of the record in either Lead I or Lead J, though, perhaps, from a level not far removed from it, and in this lead quickly turns away from its starting point in a sharp curve, without the short straight stretch which is so evident in normal records preceding the peak of the T wave. The T wave is usually of larger size than customary and accordingly shows a somewhat sharper peak. The T wave is usually turned downward in Lead 2 and in one other lead. Not all of these changes are to be found in every record, but enough of them are present to give it a characteristic appearance.

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT

FUNDS FOR RELOCATION OF PHYSICIANS

The following statement was recently released by the Bureau of Legal Medicine and Legislation of the American Medical Association.

* * *

Under the date of October 1, the President transmitted to Congress supplemental estimates for the United States Public Health Service amounting to \$4,427,550. It was contemplated that of this total \$1,000,000 would be used to supply medical care to civilians in critical areas. Such care, it was proposed, would be supplied in one of two ways: by the assignment of medical officers of the Public Health Service to such areas to treat civilians under a fee schedule agreed on by the Public Health Service and the state department of health or by inducing civilian physicians to relocate to the critical areas by paying them a relocation allowance of \$250 a month for three months, as well as moving expenses.

These estimates were referred to the House Committee on Appropriations, which refused to include in the First Supplemental National Defense Appropriation Bill for 1944 (H. R. 3598) the requested funds for supplying medical care to the critical areas and justified its action as follows:

The committee in rejecting the Budget request does not minimize the need or the seriousness of the situations which exist. It does hesitate to inaugurate a program of this character with federal funds to provide direct medical attention to the civilian population with physicians paid by the federal government. The committee has the opinion that out of the co-operative efforts of the federal government, the medical associations, the state departments of health and the communities themselves, there will and should come a concerted and spontaneous effort to provide this need. Most of it is in war-industry areas, and it is inconceivable that such communities working with the industries, the affected population, and state and local authority, cannot inaugurate and maintain an adequate public-spirited program, financially sound, to serve this need. If the affected areas cannot and will not solve their local needs it may be necessary for the federal government

in the interest of the general public health to step in, but until then the committee feels that federal funds should be withheld under the contemplated procedure.

In the Senate, H. R. 3598 was amended, at the instance of Senator Russell, of Georgia, to authorize an appropriation of \$345,000 for use by the Public Health Service in providing medical care to civilians in critical areas subject to the following conditions and restrictions:

Provided, That the Surgeon General is authorized, on application of a municipality, county or other local subdivision of government duly approved by the state health department having jurisdiction over said municipality, county or other local subdivision of government, to enter into agreements with private practicing physicians and dentists under which, in consideration of the payment to them of a relocation allowance not to exceed \$250 per month for three months and the actual cost of travel and transportation of the physician or dentist and his family and household effects to the new location, such physician or dentist will agree to move to and engage in the practice of his profession in such area for a period of not less than one year: Provided, however, That no such contract shall be made with any physician or dentist unless such physician or dentist shall be admitted to practice by the state authority having jurisdiction of such new location: Provided further, That each such applicant subdivision shall contribute \$100 to the total cost of such relocation allowance, travel and transportation costs of each such physician or dentist and his family obtained by said applicant.

The bill passed the Senate with this amendment in it. It will now be considered by a conference committee composed of representatives on the part of the House and on the part of the Senate, in an effort to adjust the differences in the bill as it passed the House and as it passed the Senate.

Copies of the *Congressional Record* for December 8, the date on which Senate action on the Russell amendment occurred, are being sent to each state medical society. This procedure is followed because of the extremely important discussion that preceded the adoption of the amendment, many senators desiring assurance that the amendment in no way involved the socialization of the practice of medicine.

MISCELLANY

AMERICAN COLLEGE OF SURGEONS

During 1943, the following physicians in Massachusetts, New Hampshire and Vermont were accepted as fellows of the American College of Surgeons:

Massachusetts: Matthew J. Bachulus, Longmeadow; Z. William Colson, Lawrence; Gordon Donaldson, Boston; Clifford C. Franseen, Newton Centre; Thomas A. Hathcock, Jr., Brighton; Paul C. Kelcher, Woburn; James A. Lamphier, Brookline; David A. Latham, Chelmsford; Ernest H. Latham, N. Chelmsford; Timothy F. P. Lyons, Boston; George L. MacKinnon, Quincy; Jacob Mezer, Brighton; Eugene L. Richmond, Worcester; Lamar Souther, Boston; John S. Sprague, Boston; John C. Tate, Longmeadow; and Ralph Zupancic, Boston.

New Hampshire: Albert E. Barcomb, Rochester; Kenneth J. Daly, Manchester; and Kenneth L. Roper, Hanover.

Vermont: Louis W. Esposito, Rutland; and Bruce B. Rolf, St. Johnsbury.

MEDICAL INFORMATION OFFICE

Major General James C. Magee, retired, former surgeon general of the United States Army, has recently assumed his duties as executive officer of the information service of the Division of Medical Sciences, National Research Council. General Magee will devote full time to the organization of a central office in the National Research Council that will collect reports and records, dealing with military medical

practice, civilian practice as affected by the war, medical education and research and the distribution of diseases. This service has been made possible by a recent grant of \$75,000 by the Johnson and Johnson Research Foundation, of New Brunswick, New Jersey, to enable the National Research Council to assemble and disseminate medical information pertaining to the war effort. This enterprise is expected to fill a long-felt need in providing up-to-date information to the medical officers of the armed services, both in this country and abroad, and in making the experience of war medicine available, so far as possible, to civilian physicians.

NOTE

On the evening of December 30, ninety-six graduates of Tufts College Medical School were awarded their degrees and the majority were simultaneously commissioned in the Medical Corps of the Army or Navy. The honorary degree of Doctor of Science was conferred on two graduates of Tufts College Medical School: Brigadier General Raymond W. Bliss, of Washington, D. C., and Dr. Sara M. Jordan, of Boston.

CORRESPONDENCE

AN OPENING IN MONTAGUE

To the Editor:—The following letter from the Governor's office is self-explanatory. Perhaps some physician may wish to take advantage of this offer.

H. QUIMBY GALLUPE, M.D., *Secretary*
Board of Registration in Medicine

State House
Boston

* * *

December 22, 1943

Dear Dr. Gallupe:

Mrs. George A. Cooke, of 813 Beacon Street, Boston (Kenmore 7956), is the widow of the only physician who was located in the town of Montague. She has made the offer of the use of the late doctor's office and equipment to any doctor who might be interested in setting up a practice in that town.

I pass this on for your information.

Sincerely yours,

[Signed] William A. McGivney
WILLIAM A. MCGIVNEY
Assistant Secretary to the Governor

State House
Boston

KÜMMELL'S DISEASE

To the Editor: In the November 18 issue of the *Journal*, appeared a medical eponym, "Kümmell's Disease," that was of special interest to me. While practicing in Hungary, I had two cases in my surgical ward—one in 1926 and one in 1928—both of which had the typical histories, symptoms and developments of Kümmell's disease, with negative tuberculin reactions and so forth. After learning from experience with the first case, I had made it a rule to immediately take x-ray films of all, even seemingly insignificant, injuries in the vertebral region. The films of the second patient, taken immediately after the accident, were entirely negative. The patient, a miner, resumed work about twelve days after the injury was incurred, but after an interval of many months developed typical gibbus formation with the usual x-ray findings. I sent the pictures and case histories to Dr. Kümmell and have on hand his reply, in his own handwriting, dated December 11, 1928. He wrote how happy he was to receive my information and that he considered it additional proof that Kümmell's disease—or as he later called it,

"post-traumatic vertebral disease"—actually existed. He also sent me the reports made by the director of the X-ray Laboratory of Hamburg University Medical School. The report on the pictures taken after the accident but without knowledge of the case history was "negative," and after the gibbus formation, "tuberculous spondylitis." After learning the history the diagnosis was changed to "typically so-called 'Kümmell's disease' or post-traumatic vertebral disease."

On Dr. Kümmell's urging, I had a paper published in 1928 about these two cases, with the x-ray pictures.

LOUIS A. SZIVET

309 Main Street
Great Barrington, Massachusetts

NOTICES

NEW ENGLAND ROENTGEN RAY SOCIETY

The next meeting of the New England Roentgen Ray Society will be held at the Harvard Club of Boston on Friday, January 21. There will be an x-ray conference from 4:30 to 6:00 p.m. on the topic "The Paranasal Sinuses." At 6:00 p.m., dinner will be served in Harvard Hall. At 8:00 p.m., the following program will be presented:

Radium in Present-Day Therapeutics. Dr. Douglas Quick.
Radiologic Problems in the Treatment of Carcinoma of the Skin (illustrated by slides). Dr. John T. Murphy.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The next written examination and review of case histories (Part I) for all candidates will be held in various cities of the United States and Canada on Saturday, February 12, 1944, at 2:00 p.m.

Arrangements will be made, so far as possible, for candidates in military service to take the Part I examination (written paper and submission of case records) at their places of duty, the written examination to be proctored by the commanding officer (medical) or some responsible person designated by him. Material for the written examination will be sent to the proctor several weeks in advance of the examination date. Candidates for the Part I examination who are entering military service or who are now in service and may be assigned to foreign duty may submit their case records in advance of the above date by forwarding them to the office of the secretary. All other candidates should present their case records to the examiner at the time and place of taking the written examination.

The Office of the Surgeon-General of the United States Army has issued instructions that men in service who are eligible for Board examinations be encouraged to apply and that they request orders to detached duty for the purpose of taking these examinations whenever possible.

All candidates will be required to take both the Part I examination and the Part II examination (oral, clinical and pathological examination). Candidates who successfully complete the Part I examination proceed automatically to the Part II examination to be held later in the year. Headquarters for the Part II examination will be the Hotel William Penn, Pittsburgh, Pennsylvania, from June 7 to 13, 1944. Notice of the exact time of the examinations will be sent to all candidates well in advance of the examination date. Candidates in service are requested to keep the secretary's office informed of any change in address. If a candidate in service finds it impossible to proceed with the examinations of the Board, deferment without time penalty will be granted under a waiver of the published regulations as they apply to civilian candidates.

Applications for the 1944 examinations are now closed.

For further information and application blanks, address Dr. Paul Titus, Secretary, 1015 Highland Building, Pittsburgh 6, Pennsylvania.

HOW TO IMPROVE THE TREATMENT OF FRACTURES*

CHARLES L. SCUDDER, M.D.†

BOSTON

IT IS appropriate to list this communication with war papers. There is no war work more important than that the medical profession should adjust itself to better results in the case of the injured. To accomplish this, and to have the hospital and the personnel of the hospital up to date when the war is over and the younger men return from the active war front, will be well worth while. It is to this end that I address you today, urging a real war effort.

Every member of the Society, no matter with what subject in medicine or surgery he is primarily concerned, should be familiar with first-aid care and transportation of the injured. The treatment of fractures, however, is very special work, and demands a doctor who has had a general surgical training. The art of surgery has been for years far in advance of all the sciences on which its future depended. Today, the sciences are overtaking the art and form the basis of sound treatment. Chronic duodenal and gastric ulcers were permitted to advance to perforation, peritonitis and fatal hemorrhage until comparatively recently. Injuries to the head, with or without fracture of the skull, invariably received a decompression operation, done by the surgeon first seeing the case. Today, one almost never hears of or sees a decompression operation because, with an increasing knowledge of the cerebrospinal fluid and its behavior following a blow on the head, especially with increasing signs, a diagnostic and sometimes a therapeutic lumbar puncture may be employed by the attending surgeon.

Fractures are now unwittingly allowed to go beyond the time at which successful treatment may be instituted. Such delay forever precludes the possibility of preventing disabling deformity. In some of these cases even death itself might be preferred to the permanent disability with which all are familiar.

The accident causing a fracture is instantaneous. The reparative processes begin immediately and

treatment should therefore begin without delay so that the reparative processes may be facilitated instead of hindered. By treating a fracture instantly, one treats the fracture alone; by treating it after delay, one treats the fracture together with its complications. Ordinarily, prompt treatment is easy; frequently, delayed treatment is difficult. Furthermore, delayed treatment is dangerous, and late treatment is lamentable.

During the course of years, fundamentals are bound to change. One cannot wish broken and displaced bones into position and cause them to unite by moral suasion, sending the patient on his way without a hitch. The methods available to the surgeon who deals with trauma are remarkable, and compel a modification of what once were regarded as fundamental principles. This is as it should be. We must not be bothered or alarmed by these tendencies; they all indicate improvement.

What can be done in Massachusetts to improve the results following the treatment of fractures? Some suggestions follow.

Proper first-aid care must be given to injured people. It is a fact of great importance that few practitioners of medicine and surgery in the United States are familiar with first aid. The war has stressed the value of first aid and has increased information about it among laymen. Physicians, in self-defense, are being obliged to learn something about it.

The injured should be immediately transported to a hospital. The American Red Cross textbook on first aid, which is used as the basis for instruction in first-aid care, is excellent. It contains more good methods of transportation than poor ones. It is not, however, perfect, and certain improvements will undoubtedly be made in subsequent editions. How should one transport to a hospital a man who has fallen from a tree and injured his back, or one with a probable broken neck? Can you answer these questions satisfactorily? You should be able to, because you may have to take care of someone who knows how these things ought to be done.

*Presented to the annual meeting of the Massachusetts Medical Society, Boston, May 25, 1943.

†Consulting surgeon, Massachusetts General Hospital.

An x-ray examination must be made to learn accurately the problem at hand. Adequate x-ray films should be taken to confirm and enlarge in detail the clinical diagnosis. I recently saw a switchman who had fallen from a boxcar and complained of pain in the back. Perfect x-ray films had been made, but for the sake of economy the films had been taken only from the second lumbar vertebra down to include the upper third of the femur. The patient was treated for seven weeks by rest in bed because there were no evidences of fracture in the parts x-rayed. After working for a month, he again complained of pain in the back. New x-ray films were taken, including the whole lumbar spine. A compression fracture of the first lumbar vertebra was seen and treated. This lesion was missed in the first instance because of inadequate x-ray films.

The doctor must evaluate his ability to treat the injury. Suppose that he is examining a child with a fracture of a long bone, having been called by the parents. Why was he called? The ordinary reason given is that he is regarded as the family doctor. He delivered the mother of this family of all her children. The mother says, "We have confidence in you." It is true that he has been caring for this family for years. But the notion that any doctor can treat a fracture is less prevalent than it used to be. This imaginary case raises the question of the competency of a doctor to treat a fracture. There should arise in his mind the questions, "Am I prepared to treat this fracture? Do I know how to find out exactly what the damage is? Am I competent to decide what is to be done in this particular case, and to do it?" The doctor may say to himself, "I need the money. I can take care of this fracture. The family thinks I am able, and that is a great asset. I will make a bluff at it, and if I get stuck, I shall call for help." Under the economic conditions of today, it may be difficult for a doctor to give up such a case.

If the physician is unable to give proper treatment, he must call a good consultant as soon as possible. By securing advice early, he may prevent a Volkmann's contracture. To cite an example, in a town not far from Boston, I held a fracture clinic. Cases were brought to the clinic from outlying districts. Seven children came in, each with an established Volkmann's contracture following a supracondylar fracture of the humerus. No splints or bandages had been used. These cases point a moral and dramatically accentuate the importance of properly treating injuries in the region of the elbow joint. Each of these bad results might have been avoided. Unwarranted responsibility is a risk to the patient and to the reputation of the doctor. If the attending physician asks for an early consultation, he gives both his patient and the consultant a better chance. He rises in the esteem of his patient and in the good will of the community in which he practices.

Associated injuries must be recognized. The fracture of the bone in any case may be the least important of the injuries received. There may be injuries to the brain, spinal cord, or lung, with an associated pneumothorax or a hemopneumothorax; injuries to the abdominal viscera, with hemorrhage into the abdominal cavity, and possibly with rupture of the viscera; or injury to the urinary bladder, associated with fractures of the pelvis.

One does not have to qualify as a neurosurgeon, a thoracic surgeon, a genitourinary surgeon, an abdominal surgeon, an orthopedic surgeon or a vascular surgeon, but anyone treating a fracture should be familiar with the fundamentals of these special branches of surgery so that he may know when there is need for consultation with a specialist.

In treatment, the doctor must use a method with which he is perfectly familiar. If a surgeon has been securing good functional results by the use of certain methods, he should by all means continue to use them. Nevertheless, I wonder how many of you are familiar with your results in the treatment of fractures.

One should be conversant with known operative procedures and results. There are fractures that should be treated initially by operative methods when the local equipment is available and intelligently used.

One should be familiar with nonoperative treatment. Nonoperative methods may require great skill. Their results are often brilliant.

More pull and less manipulation should be employed in treating any fracture. Far greater initial traction should be used, for sufficient traction may bring about reduction of the fracture. Instead of using 5 or 10 pounds of traction at the beginning of treatment, and gradually increasing it, ordinarily one should begin with 25 or 30 pounds.

The period of aftercare or convalescence is a time of great importance. This should be regarded as a time of active treatment. One reason for Dr. Otto Hermann's successful treatment of fractures of the os calcis at the Boston City Hospital is dependent in great measure on his supervision of the minute details of the aftercare of these cases. In the convalescing period one may profitably spend a little time instructing the patient in muscle re-education, weight bearing, correct shoes, exercises and the use of crutches, and may thus gain the patient's confidence and directly influence the result of treatment.

In the United States and in the provinces of Canada, the American College of Surgeons has already established ninety regional fracture committees, with the object of improving fracture treatment in these communities. Obviously, certain states have more than one committee. Texas, Pennsylvania, New York, Indiana, and California are splendidly organized, and are accomplishing much. Massachusetts has a regional committee, with sixteen subcommittees, in Lowell, Beverly,

Quincy, Northampton, Gardner, Melrose, Haverhill, Cotuit, Brockton, Greenfield, Taunton, Worcester, Newburyport, New Bedford, Springfield and Pittsfield, which carry on their work through the local hospitals. During the past week, I received a report on the activities of the Flint (Michigan) regional committee, which reads as follows:

We have had fracture conferences of my staff each Friday, from 4.30 to 6.30 p.m. All fracture problems of the previous week are discussed at these meetings, and they represent 85 per cent of the cases of fracture admitted to the Hurley Hospital. Similar meetings are held at selected intervals for the Fracture Service of St. Joseph's Hospital in this city. All fracture cases are assigned to members of the fracture services, and these are presented, both formally and informally, as the need arises.

All the ambulance drivers have received adequate first-aid instruction through various agencies, and each ambulance is equipped with splints, which, with few exceptions, are properly used. Patients are being brought to the hospitals with some type of splinting apparatus, usually a Thomas splint for the lower extremity, and a Murray-Jones splint for the upper extremity.

Fracture cases of all kinds at Hurley Hospital from July, 1941, to July, 1942, numbered 1085. About eighty per cent were handled by my staff and myself, either as staff or private cases, and the remainder were cared for by surgeons handling the occasional fracture. The latter situation is unavoidable inasmuch as Hurley Hospital is an open hospital. However, we are able to control the minor percentage by example, and through the co-operation of the X-ray Division. These patients are, in our opinion, handled according to the prevailing standards that we have been able to establish by this persistent method of fracture education in this community over the past twelve years.

We keep a book in which every fracture admitted to the hospital is tabulated. We also keep a conference book, in which important comments during reviews of the x-ray films are noted. Furthermore, pertinent recent information regarding this division of surgery is posted on a bulletin board in the emergency room for the Department of Traumatic Surgery. We manage to keep one live research problem under way each year.

We have nine members on the regional fracture committee.

I believe that your personal co-operation with the several regional fracture subcommittees in Massachusetts along the lines suggested in this report from Flint, Michigan will help very much in improving the results of fracture treatment. Find out who is the chairman of the subcommittee nearest your town. If you are a consultant at the local hospital and if you are on active duty there, try to initiate a follow-up of the cases of fracture, and analyze these results at some regular staff meeting, showing the x-ray films. It makes no difference how few cases of fracture are treated at your hospital. These cases should be carefully studied by the whole staff. Invite doctors to the hospital meetings so that all in your community may profit by a review of the cases. Consider seriously the ten or twelve suggestions I have made as guides. There is no reason why Massachusetts should not stand abreast of the advances taking place in fracture treatment at this time. Each one of us can help.

DIVERTICULITIS OF THE COLON*

A Review of the Literature and an Analysis of Ninety-One Cases

EDWARD L. YOUNG, M.D.,† AND EDWARD L. YOUNG, III, M.D.

BOSTON

DIVERTICULUMS of the large bowel were noted by Friend as early as 1730, but a disease entity was not ascribed to them until Cruveilhier's work in 1849. Ten years later the first report of a complication of rupture—a sigmoidovesical fistula—was made by Jones, but little attention was paid to the condition until W. J. Mayo¹ in 1907 described resection of the sigmoid in 5 cases of chronic obstructive diverticulitis. The value of the roentgen ray as an aid in diagnosis was not fully appreciated in this country until 1915.² Since then there has been a gradual evolution in the technic of handling these cases—from radicalism to conservatism. The disease is of relatively common occurrence, errors in diagnosis are not infrequent, and both the morbidity and mortality are altogether too high.

INCIDENCE, AGE AND SEX

The incidence of diverticulosis of the colon—a prerequisite of diverticulitis—has been estimated

at 3 to 10 per cent. A compilation of statistics³⁻⁶ shows an incidence of 5.2 per cent in 70,572 colons examined by barium and autopsy. It is difficult to obtain significant figures on the percentage of cases of diverticulosis progressing to diverticulitis. It is usually stated that from 12 to 15 per cent do so, but in three series totaling 3915 cases with diverticulosis of the colon the incidence of diverticulitis was 34.3 per cent.^{6,7}

Of patients with diverticulitis about 22 per cent are operated on.⁸⁻¹² Because, however, of the trend in treatment away from surgery and the significant number of patients operated on with erroneous diagnoses, the actual percentage of cases of diverticulitis reaching the operating table is probably lower than this. Arnheim¹³ collected from the literature 3399 cases of diverticulitis and found complications that might have necessitated surgery in 15 per cent—perforation with abscess formation or general peritonitis, peridiverticulitis with formation of a tumorlike mass, and sigmoidovesical fistula.

Diverticulitis is primarily a disease of adult life. Brown¹⁰ has estimated that only 0.3 per cent of all

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 25, 1943.

†Wilding surgeon, Massachusetts General Hospital; surgeon-in-chief, Faulkner Hospital.

An x-ray examination must be made to learn accurately the problem at hand. Adequate x-ray films should be taken to confirm and enlarge in detail the clinical diagnosis. I recently saw a switchman who had fallen from a boxcar and complained of pain in the back. Perfect x-ray films had been made, but for the sake of economy the films had been taken only from the second lumbar vertebra down to include the upper third of the femur. The patient was treated for seven weeks by rest in bed because there were no evidences of fracture in the parts x-rayed. After working for a month, he again complained of pain in the back. New x-ray films were taken, including the whole lumbar spine. A compression fracture of the first lumbar vertebra was seen and treated. This lesion was missed in the first instance because of inadequate x-ray films.

The doctor must evaluate his ability to treat the injury. Suppose that he is examining a child with a fracture of a long bone, having been called by the parents. Why was he called? The ordinary reason given is that he is regarded as the family doctor. He delivered the mother of this family of all her children. The mother says, "We have confidence in you." It is true that he has been caring for this family for years. But the notion that any doctor can treat a fracture is less prevalent than it used to be. This imaginary case raises the question of the competency of a doctor to treat a fracture. There should arise in his mind the questions, "Am I prepared to treat this fracture? Do I know how to find out exactly what the damage is? Am I competent to decide what is to be done in this particular case, and to do it?" The doctor may say to himself, "I need the money. Obviously, certain states have more than one committee. Texas, Pennsylvania, New York, Indiana, and California are splendidly organized, and are accomplishing much. Massachusetts has a regional committee, with sixteen subcommittees, in Lowell, Beverly,

enema arc used in arriving at a diagnosis. A negative examination by either method does not, however, exclude a diagnosis of diverticulitis. Only rarely can diverticular openings be seen with the sigmoidoscope, but there are definite changes in the bowel suggestive of the diagnosis — spasm, hypermotility with varying degrees of obstruction, immobility, sharp angulation, mucosal edema and signs of an extraluminal mass. Jackman and Pumphrey²³ made a correct diagnosis of diverticulitis in 66 per cent of a series of cases from sigmoidoscopy alone. Diverticula were seen, however, in only 14.5 per cent. Brown and Marley¹¹ found that suggestive evidence could be discovered by sigmoidoscopy in only 24 per cent of 218 cases, and diverticular openings in only 9 per cent.

The barium enema is the most accurate diagnostic procedure. Figures on the percentage of accuracy are practically nonexistent. In a series of 30 cases reviewed by Graham,¹⁶ diagnosis by x-ray was correct in only 57 per cent, indeterminate in 17 per cent, and wrong in 26 per cent. Of the cases that were wrongly diagnosed, 4 were called diverticulitis; 3 of these were later proved to be cancer, and 1 proved to be normal. Three were diagnosed as cancer and later proved to be diverticulitis; and 1 was diagnosed as normal and later proved to be diverticulitis. Morrison²⁴ believes, however, that well over 90 per cent of diverticula can be seen. The differentiation of diverticulosis and diverticulitis cannot always be made at examination, but this seems to be largely due to the fact that patients are not studied by barium enema during the clinically inflammatory stage. In obstructive cases the differentiation of carcinoma and diverticulitis is often extremely difficult.¹²⁻²⁷ X-ray films show uncomplicated diverticula as rounded outpocketings filled with barium in relief along the border of the bowel wall.

Diverticulitis is manifested by spasm, by hypermotility with varying degrees of obstruction due to fibroblastic reaction or by spasm. Tenderness may or may not be present.

TREATMENT

As with any disease, the best treatment is prophylaxis. Following a diagnosis of diverticulosis, measures should be instituted to avoid the factors known to predispose to diverticulitis, such as overdistention of the bowel, hard, coarse fecal material, degenerative changes and obesity. A low-roughage diet and sufficient mineral oil or other bland laxative to promote regular, soft-formed movements eliminate the usual mechanical factors. Tincture of belladonna to relieve spasm is always beneficial. All irritative cathartics are contraindicated, especially strong saline solutions since their prolonged use leads to hypertonicity of the rectal sphincter. All efforts should be aimed at cultivation of regular bowel habits.

With the onset of diverticulitis, further steps are indicated — a temporary soft diet to rest the inflamed sigmoid, bed rest, local heat and antispasmodics. There are several methods of applying heat locally — hot stupes to the abdomen, the Elliott method and warm colonic irrigations. Roberts²⁸ and Friedenwald²⁹ mention the use of large barium enemas in both subsiding and acute diverticulitis. One of us (E. L. Y.) has used repeated small instillations of dilute barium with excellent results. The method is as follows in acute cases: 30 gm. of x-ray barium in 90 cc. of warm water is instilled rectally twice a week, following a cleansing enema, until subsidence; then once a week as long as the forbearance of the patient lasts. Kimpton³⁰ uses barium by mouth with the same timing. The barium fills the diverticulum, shutting out irritating feces, and is itself mildly soothing.

As noted above, about 22 per cent of cases come to surgery, but indications for surgical intervention are still unsettled and the trend in therapy is toward conservatism. There seem to be five general indications for surgery: acute perforation with spreading peritonitis, sigmoidal obstruction, formation of a fistula, a localized abscess and inability to differentiate diverticulitis and cancer. Technical details covering the choice of the time to operate and the procedure to be adopted are too varied to warrant discussion here; the reader is referred to the excellent review by Laufman.³¹ Graham¹⁶ has emphasized the two cardinal principles: restoration of chemical balance while using the expectant measures of bed rest, local heat, sedatives and proper control of intake, and the simplest operative procedure. The importance of the latter principle is amply proved by figures collected by Laufman. In a series of 434 patients, there was an operative mortality of 11.8 per cent following conservative procedures, — colostomy alone, colostomy and subsequent closure, cecostomy, drainage of abscess, exploratory laparotomy, separation of adhesions, excision of inflamed diverticula and repair of colovesical fistulas without resection, — as against a mortality of 21 per cent following radical procedures — resection after colostomy, Mikulicz resection, resection and anastomosis after colostomy, obstructive resection with subsequent closure of colostomy and one-stage resection.

Results. It is impossible to estimate the prophylactic value of measures undertaken when diverticulosis alone is present. Brown and Marley¹¹ made a follow-up study of 192 patients with diverticulosis who had followed a careful medical regime. Of these, 145 had had no symptoms suggestive of diverticulitis, 46 had died of unrelated or unknown causes, and 1 had died of "questionably" related causes. They likewise reviewed 238 cases of diverticulitis treated on a medical regime. Of these patients, 118 (50 per cent) were "cured," 23 per cent were not affected, and 4 per cent died of related causes.

From a review of the literature, Laufman³¹ has concluded that of any large series of cases 18 per cent receive no benefit from any form of therapy and the mortality is 16 per cent. The latter figure coincides with the latest one (14 per cent) reported by Lockhart-Mummery.³²

* * *

The following sections and Table 1 are based on a series of 84 cases of diverticulitis of the sigmoid seen at the Faulkner Hospital from 1933 to 1942, inclusive. For analytical purposes the cases have

TABLE 1. *Signs, Symptoms and Findings in Chronic and Acute Diverticulitis*

SIGN, SYMPTOM OR FINDING	CHRONIC DIVERTICULITIS	ACUTE DIVERTICULITIS
	%	%
Change in bowel habits	79	46
Rectal bleeding	33	20
General digestive complaints	53	41
Pain	63	95
Tenderness	63	93
Elevated temperature	12	80
Elevated white-cell count	19	80
Positive sigmoidoscopic findings	71	—
X-ray diagnosis (barium enema):		
Diverticulosis	98	88
Diverticulitis	78	84

been divided into chronic and acute, as determined principally by the presenting complaint, immediate history, physical examination and white-cell count, and partly by the known duration of the colonic disease.

INCIDENCE

During 1941 and 1942, barium enemas were given to aid in the diagnosis of abdominal symptoms in 423 cases, and diverticulosis of the colon was demonstrated in 154 (36 per cent). In 89 (58 per cent) of these, diverticulitis was shown by x-ray examination. Both the percentage of diverticulums found and the number of these patients having diverticulitis are much higher than those found in the literature. The suggested explanation—namely, that this disease is much more frequent than is generally supposed—gives it a more prominent place than it usually receives.

CHRONIC DIVERTICULITIS

The distinction between mild, chronic diverticulitis and diverticulosis is often a debatable one. In the 43 patients with chronic diverticulitis have been included those with a clinical and x-ray diagnosis of diverticulitis and a history consistent with diverticulitis, together with x-ray evidence of a diverticulum, with or without attendant irritability and tenderness or spasm of the colon.

Age and sex. The ages ranged from thirty-seven to eighty-one years, with 88 per cent of the cases divided equally between the fifth, sixth and seventh decades. Twenty-four (56 per cent) of the patients were women.

History. A change in bowel habits was the outstanding complaint in 34 patients (79 per cent).

There was constipation in 14 cases, diarrhea in 7 cases, and both in 6 cases. Gross bleeding was present in 9 cases, and occult blood in 5. Excluding 1 case of gross bleeding from carcinoma, the incidence of rectal bleeding due to diverticulitis was 33 per cent. Of the 9 patients without changes in bowel habits, 2 complained of indigestion, 2 of lower abdominal pain, 1 of pain in the left lower quadrant, 1 of pain in the right back, and 3 of general debility, loss of strength and anorexia. The patients with indigestion had associated diaphragmatic hernias, and one with low abdominal pain had ascites on a cirrhotic basis. One patient had relief of low abdominal pain from defecation.

The next most frequent complaints were abdominal pain (27 cases, or 63 per cent) and general digestive disturbances, such as gas, indigestion, nausea and vomiting (23 cases, or 53 per cent). There were other scattered symptoms such as loss of weight (5 cases), loss of strength and appetite (6 cases) and urgency and nocturia (2 cases).

Physical examination. Abnormal physical findings were minimal. Sixteen patients (37 per cent) had negative examinations (excluding other disease). Twenty-seven had abdominal tenderness, usually mild but occasionally marked and with spasm. This was below the umbilicus in 18 cases, in the left lower quadrant in 13, in the right lower quadrant in 3, throughout the lower abdomen in 2, in the left upper quadrant in 4, on the right side in 2, and diffuse in 1; the pain was not localized in 2 cases. A mass was made out rectally in 3 cases, in one of which it proved to be carcinoma, vaginally in 1, and in the left lower quadrant in 2. Distention was noted in 4 cases.

Temperature and white-cell count. These corresponded to the mildness of the symptoms and signs. Thirty-eight patients (88 per cent) had normal temperatures; in the remainder the temperature never went above 100°F. and rapidly fell to normal. The white-cell count was normal (below 10,000) in 35 cases (81 per cent) and below 13,500 in the remainder.

Sigmoidoscopy and barium enema. Sigmoidoscopy was done in 7 cases. No diverticulums were seen, but there was evidence suggestive of the diagnosis in 5 of these (71 per cent)—spasm of the lower sigmoid and rectum in 4 and a mass in 1.

Barium-enema studies were done in 41 cases and a roentgenologic diagnosis of diverticulitis of the colon was made in 32 (78 per cent). Diverticulums were seen in another 8 cases (20 per cent). Diverticulums were seen in the descending colon in 19 cases, in the transverse colon in 13 and in the ascending colon in 8. There were four partially correct or totally erroneous diagnoses. Two cases diagnosed as carcinoma of the sigmoid proved at operation to be diverticulitis; 1, diagnosed as diverticulitis, proved at autopsy to be diverticulitis and carcinoma of the rectum; 1, diagnosed as diverticulitis, proved at autopsy to be diverticulitis and carcinoma of the

rectum; 1, diagnosed as obstruction of the lower sigmoid was operated on for carcinoma and proved to be diverticulitis; and 1, diagnosed as abscess cavity, proved at operation to be due to diverticulitis. Thus, x-ray studies with a barium enema in the chronic group may be said to be 98 per cent correct in determining the presence of diverticula of the colon. The actual diagnosis of diverticulitis is, in the mild cases at least, of little significance for two reasons: the enema may be given after subsidence of the acute stage, and the clinical picture as seen by the physician during the acute stage supported by x-ray evidence of a diverticulum should be sufficient for a diagnosis.

Treatment. Seven operations were performed (excluding a case with known diverticulitis of the sigmoid but with a carcinoma of the rectum in addition), making an operative incidence of 16 per cent. Two patients were explored because of inability to make a differential diagnosis between diverticulitis and carcinoma, and one of these had resection preceded by transverse colostomy. Three were operated on with a diagnosis of carcinoma of the sigmoid with resection in one, a two-stage Mikulicz resection in another, and drainage of an abscess in the third. One patient was operated on for lysis of adhesions diagnosed preoperatively as diverticulitis, 1 for evacuation of an abscess obstructing a previous suture line (from resection for carcinoma of the splenic flexure) that proved to be due to a ruptured diverticulum. One patient died of massive pulmonary collapse, a mortality of 14 per cent.

The procedures used for the 4 erroneously diagnosed cases were colostomy followed by resection, a two-stage Mikulicz resection and drainage of abscess (two cases).

The hospital stay averaged eight days for the nonoperative cases and twenty-seven days for the operative ones—excluding the case of resection of the splenic flexure.

ACUTE DIVERTICULITIS

In the 41 cases of acute diverticulitis, as compared with the chronic cases, there was intensification of symptoms and signs, more operations were done, and the mortality was higher.

Age and sex. The age distribution was a decade younger than in the previous groups, 85 per cent of the cases occurring between forty and sixty-nine. There was a slight preponderance of males (51 per cent).

History. Pain was the chief complaint in 39 cases (95 per cent), in 24 of which it was below the umbilicus. It was in the left lower quadrant in 16 cases and hypogastric in 8, in 3 of which it was most marked in the right lower quadrant. There were several striking examples of the fallibility of localization of pain as indicating the site of disease. One patient had midepigastria pain, 1 in the right upper quadrant, 1 in the left testicle and 1 in the vagina.

Only 19 patients (40 per cent) had a change in bowel habits, and 16 of these stated that the change was directly associated with the present entry. There was obstipation of one to several days' duration in 6 cases, an urge to defecate without results in 3, and relief of pain on defecation in 3. Gross bleeding was present in 4 cases, and occult blood in 4, making an incidence of bleeding of 20 per cent.

There were digestive complaints in only 17 cases (41 per cent), with vomiting in 11, nausea with or without vomiting in 8 and anorexia in 3.

Urinary symptoms became more prominent in this group, occurring in 8 cases (20 per cent). Four of these patients had burning or sharp pain on urination; 1 patient had urgency and frequency. Other symptoms were pressure and pain around the bladder and vagina.

Physical examination. Thirty-eight patients (93 per cent) had abdominal or pelvic tenderness, in 31 below the umbilicus; the tenderness was greatest in the left lower quadrant in 21 and in the right lower quadrant in 6. One had tenderness in the right upper quadrant, and 5 on rectal or vaginal examination. Distention was present in 18 (44 per cent). A mass was felt in 16 cases (39 per cent)—in the left lower quadrant on abdominal examination in 10, and on rectal or vaginal examination only in 6.

Temperature and white-cell count. The temperature was elevated in 33 cases (80 per cent), rising to 100°F. or less in 14, to 101°F. in 11, and to 102°F. in 4. In 1 case it reached 103.8°F. The white-cell count was likewise elevated in 33 cases, reaching 12,000 in 7, 15,000 in 10, 20,000 in 10, 30,000 in 3, and 33,000 in 1.

Barium enema. No sigmoidoscopic examinations were done. A barium enema examination was done in 25 cases (61 per cent). In 21 of these, the diagnosis was diverticulitis and 1 diverticulosis in a spastic sigmoid; in the other 3 it was spastic bowel, complete obstruction at the junction of the descending colon and sigmoid and an obstructive lesion at the midsigmoid, respectively. The last case was diagnosed as diverticulitis by barium enema four days later, the first two at operation. Obstruction was present in 5 cases—complete in 3 and partial in 2. Barium was seen outside the bowel in 2 cases, and in both there was complete recovery without operation then or later.

Treatment. Proctoscopy was done in 1 case and a mass pressing on the lumen of the lower bowel was noted. Surgical procedures were carried out on 21 patients (51 per cent), with errors in diagnosis in 6 cases and a mortality of 19 per cent. The erroneous diagnoses were acute appendicitis, twisted ovarian cyst (3 cases), ectopic pregnancy and carcinoma of the sigmoid. The last case was operated on primarily for fibroids. A mass in the sigmoid was found and was believed to be carcinoma. Colostomy was done, and at a second operation resection was performed; no carcinoma was found. Simple drain-

age was carried out in 9 cases, colostomy in 2, a one-stage resection in 1, and a Mikulicz resection in 2. Three patients died within ten days of operation, of embolus; 1 died seven years later as a result of a chronic draining pelvic abscess.

SUMMARY AND CONCLUSIONS

A brief review of the literature on diverticulitis of the colon is given, and the symptoms, signs and treatment of 84 cases at the Faulkner Hospital are presented.

Certain facts stand out as important: blood in the stool was found in 26 per cent of the cases where no cause other than the diverticulitis was found; the incidence of this condition was much higher in this series than in others, which suggests that in a true cross section of disease as seen by the general practitioner the condition should be oftener recognized and treated; conservative treatment, especially the use of x-ray barium either by mouth or where possible by rectum, gives a high percentage of relief; and when surgery is needed the simplest procedure possible gives the lowest mortality.

TRANSIENT NERVOUS HYPERTENSION AS A MILITARY RISK*

Its Relation to Essential Hypertension

WATSON F. ROGERS, M.D.,† AND COMMANDER ROBERT S. PALMER, MC-V(S), U.S.N.R.‡

BOSTON

A COMMON problem is that of male adults between the ages of twenty-one and forty-five, usually in the twenties, well qualified personally and physically for service in the armed forces except for transient elevations of the blood pressure. The systolic pressure varies from 140 to 160 mm., and occasionally higher, and the diastolic pressure ranges from 95 to 110, and rarely as high as 120. About one third of the subjects have only systolic hypertension. Occasionally nervous hypertension has previously been noted by the family physician or an insurance examiner or at a routine school or college examination. As a rule this hypertension was transient. Frequently the subject is activated and energetic, perspires freely, and has a slight to moderate tachycardia and a slight tremor. He resembles slightly a patient with hyperthyroidism. He is anxious to serve and is afraid his blood pressure will keep him out. In the more marked cases, the applicant is positively conditioned to the determination of his blood pressure. The presence of the examiner or even the sight of the sphygmomanometer causes a feeling of tenseness, sweating, tachycardia, sometimes hyperpnea, erection of the hairs and also a rise in blood pressure. In short, one observes a total sympathetic adrenergic response. With rest and reassurance the blood pressure descends, and one obtains readings within normal limits early and late in the day for three successive days.

During one month at the Office of Naval Officer Procurement, Boston, 222 (14 per cent) of 1574 applicants had mild variable hypertension at the initial examination. This is the expected incidence. One of us (R. S. P.¹) found early variable hypertension in 10 per cent of 3598 college men. Two other unpublished observations on smaller series showed 11 per cent in a mixed group of normally employed white-collar workers aged twenty to seventy, and 12 per cent among male graduate students.

Applicants with nervous hypertension are men aged from eighteen to fifty, the majority being in their twenties or thirties. Organic changes as

judged by the history, physical examination and urine examination are absent. The blood pressure itself is transiently elevated rather than transiently normal, as in early, true essential hypertension. Slightly over half the subjects have a family history of degenerative vascular disease in one or at the most two parents, grandparents or siblings. A random sampling of 26 applicants with nervous hypertension showed that 14 had both systolic and diastolic hypertension, 10 had a systolic hypertension only, and 2 had diastolic hypertension only. In 12 of the cases with systolic and diastolic hypertension the blood pressure fell, with an average drop of 19 systolic, 14 diastolic, to normal on the second or third day, and in 7 of the 10 with systolic hypertension it fell, with an average drop of 14, to normal. In 1 of the 2 cases with diastolic hypertension the blood pressure returned to normal. Its response to exercise and to change of position was not significantly different from that of normal controls.

Of cold tests² on 27 of this group, in 6 there was a fall of either systolic or diastolic pressure or both. In the others the average rise in diastolic pressure was 12, only 4 men showing a rise of 20 or more. A control series of tests on 18 miscellaneous hospitalized patients without cardiovascular disease showed an average systolic rise of 11, with a fall of 5 in one, and an average diastolic rise of 15. Only 3 showed a systolic rise of 20 mm. or more, and only 4 a diastolic rise of the same degree. On the other hand, cold tests on 30 patients with definite though mild, benign essential hypertension with minimal organic changes all showed definite pressor responses, the average systolic rise being 26, and the pressure response was 20 or more in 20 patients. The average diastolic rise was 18. It is evident that definite essential hypertension, although mild, is associated with greater and more persistent pressor responses to cold than is nervous hypertension in a random sampling of applicants. However, a rise of the blood pressure above accepted limits, even when transient, at the very least indicates that the subject has a greater chance of showing hypertension at later physical examinations.^{1, 3, 4} Hyper-reactors to mental stress incident to military physical examinations, like hyper-reactors to the cold test,² may be considered to be potentially hypertensive. Statistical studies suggest that even when blood pressures are within generally accepted normal limits, persons with pressures at the lower limits of normal are less likely to develop subsequent hypertension than are those with pressures at the upper

EQUINE ENCEPHALITIS

Many of the epizootiologic and epidemiologic characteristics of equine encephalitis have been clarified by the great amount of research accomplished in this disease in the last ten years. It is still uncertain, however, whether horses, wild and domestic fowls or other animals serve as the principal reservoir for human infection. It is quite possible that the horse is merely a chance victim, like the human being, and plays little part as a reservoir of the virus. Circumstantial support of this view is given when one considers the fact that in the last few years the incidence of equine encephalitis in horses has dropped considerably, whereas, largely because of better diagnostic facilities and reporting, recognized cases in human beings have increased.⁷ It is difficult to conjecture a comparison of equine and human infection prior to the use of adequate diagnostic methods.

The declining incidence of the disease in horses within the last few years has been developing a false sense of security in the minds of many horse owners. The reasons for this decline are difficult to evaluate when one considers the recent widespread use of equine vaccination, as well as possible biologic variables, such as decreased pathogenicity of the virus and fewer reservoirs or vectors. A somewhat analogous situation exists in human beings with such diseases as smallpox, diphtheria, measles and scarlet fever.

It is sound preventive medicine to reduce to a minimum, whenever feasible, the probable reservoirs of infection. In view of the still incomplete knowledge concerning the inter-relation of equine and human infection, it would be unwise to relax the effective preventive measure, intradermal chick-embryo vaccine, as applied to horses. An unvaccinated, highly susceptible horse population may well cause serious consequences in human beings. An official recommendation by the health officer to recalcitrant horse owners in his district to have horses vaccinated properly by a veterinarian would, therefore, be well within the province of his duty to the community.

RABIES

Few diseases can cause such public clamor for action as can an outbreak of rabies. Regulations concerning rabies control, too often unenforced, differ widely in various communities. A workable plan that will satisfy the public demand as well as the requirements of prevention is highly desirable.

Webster⁸ states in his excellent book on rabies, "His [the veterinarian's] skill and efforts in recognizing early rabies constitute a potent first line of attack in the control program." The advantages of facilities for the isolation and clinical observation of suspected rabid dogs, afforded by the veterinarian to the health officer, can be well appreciated.

Furthermore, in another highly important phase of the rabies-control program—the vaccination of dogs—the veterinarian and health officer can work together.

Until last year, the efficacy of prophylactic rabies inoculations in dogs with biologic products that had been in the market was rightly questioned. The biologically significant experiments of Leach and Johnson,^{9, 10} however, speak well for the effectiveness of a practical single-inoculation procedure. The work of Webster and Casals¹¹ shows great promise of yielding an even more effective marketable vaccine. Health officers, therefore, who were formerly hesitant about advising annual vaccination can now recommend a vaccine of proved potency as part of their control program.

Many progressive health departments advise the annual vaccination of dogs on a voluntary basis. Veterinarians are employed for a few days each year, and the cost to the dog owner is nothing more than that of the vaccine. Unless the project is well advertised, the co-operation on the part of the owner is usually fairly poor. For a really effective preventive program the following procedures should be enforced: elimination of stray dogs, proper restraint of dogs when outside the house, licensing of all dogs and compulsory annual vaccination. The first has become more difficult to practice because of the lack of personnel. The second is hard to enforce except in rabies scares. A combination of the last two can do much to offset the effect of the first two because of the intimate association with the dog that, when the dog's statement be required, certifying that the dog is vaccinated with an approved vaccine, vaccination can be enforced by a veterinarian employee.

There are several diseases that are often countered by veterinarians, of which the health officer should be aware.

Leptospirosis. This is a disease that is being increasingly recognized by veterinarians. *Canicola*, which is much more common than is *L. icterohæmorrhagiae*.

Ornithosis. The discovery of this disease in a yard fowl¹² may indicate another source of infection for the health officer. At present, the diagnosis of ornithosis by the local veterinarian with the means at his disposal is difficult. Possibly future investigations will overcome this obstacle.

Listerellosis. The natural mode of transmission of this disease, which sporadically attacks cattle, sheep, goats, chickens and human beings, is still unknown.

Tick infestation of dogs. As is well known, the wood tick and American dog tick commonly infest dogs.

festing dogs in this country are carriers of the rickettsial organism that causes Rocky Mountain spotted fever. The questioning dog owner may be referred to the veterinarian to help solve the problem of deticking his dog.

Food Sanitation. A recommendation by health officers for the inclusion of veterinarians on local boards of health should prove advantageous. The veterinarian's knowledge of food sanitation—as evidenced by the work of the Veterinary Corps of the United States Army—and disease control would be valuable in the effective performance of a board's duties.

SUMMARY

Various ways in which the veterinarian can be of assistance to the health officer are discussed, and increased utilization of the former by the latter is recommended.

MEDICAL PROGRESS

TUBERCULOSIS

JOSEPH D. WASSERSUG, M.D.*

SOUTH BRAINTREE, MASSACHUSETTS

TUBERCULOSIS is a disease of many different phases and, unless arbitrary boundaries are established in advance, discussion of the subject could continue endlessly. This year, even more than in the past, emphasis falls on the war and its relation to tuberculosis. Commenting with some skepticism on the predicted decline in tuberculosis mortality, King,¹ nine months before Pearl Harbor, pointed out that "war may upset all calculations." Fortunately, the death rate from tuberculosis in the United States has continued to fall,^{2, 3} but war-time experience in other countries^{2, 4, 5} compels one to temper optimism with caution.

TUBERCULOSIS AND THE WAR

The impact of the war on tuberculosis can be resolved into two main components. The first—case finding on an astounding and unprecedented scale—tends to lower mortality. The second—depletion of personnel in sanatoriums⁶—results in a reduction of the number of beds available for treatment and thus acts in the opposite direction. The resultant of these components depends on their

*Assistant physician, Norfolk County Hospital

magnitude and direction. But only the crudest estimates of these forces are as yet available.

Tuberculosis in the armed services. At present a satisfactory chest x-ray examination is required of all men and women accepted for service with the armed forces.⁷ During the early period of mobilization only three of the nine corps areas x-rayed all the men inducted. Because x-ray photographs were not taken of everyone, it is estimated that between 5000 and 15,000 persons with tuberculosis were taken into the Army during the fall and winter of 1940. This situation rapidly improved, however, and by March, 1941, 51 per cent of all the men called to induction centers received x-ray examinations. Three months later the Adjutant General ordered the inclusion of chest x-ray films of all registrants appearing before induction boards. On January 22, 1942, the order was further modified so that an x-ray examination became a requisite for all applicants for voluntary enlistment as well as for inductees.

As a result of official recognition of the value of the x-ray, tuberculosis case finding has proceeded at a pace hardly believed possible. Many reports of tuberculosis surveys among inductees are now

available. Rowntree and his associates⁸ found 114 cases of tuberculosis in a group of 19,923 Selective Service registrants between the ages of twenty-one and thirty-six—an incidence of 5.7 per 1000 examined. In a second analysis of 45,585 registrants, aged eighteen to nineteen years, 6.8 cases per 1000 examined were rejected because of tuberculosis.⁹ For Negroes, eighteen and nineteen years old, tuberculosis was tenth as a cause for rejection, the rate being 9.7 per 1000; it was lower in rank for Whites, accounting for the rejection of 6.6 per 1000 registrants. For the age group of twenty years and older tuberculosis was ninth in rank for both Whites and Negroes.

Statistics from the Navy have also been reported.¹⁰ Of a total of 247,253 x-ray films taken at seven Navy training stations and Marine bases, 273 (1.2 per 1000) showed active tuberculosis whereas 786 (3.2 per 1000) were regarded as inactive. Of course, these figures do not reflect the true incidence of tuberculosis, since additional cases, discovered by history and examination, were eliminated at local recruiting centers.

Since Canada has been at war longer than the United States, the experience of the Canadian Army should be of interest. The 14-by-17-inch celluloid film has been adopted by them because of its availability and on the theory that "the cheapest method is the one that is most accurate."¹¹ In one survey of 400,000 men, examined from September, 1939, to March, 1942, 3969, or 1 per cent, were rejected because of tuberculosis.¹² During this same period 114 men developed the disease. Ten of these men had entered the army in the early days before chest x-ray films were required. Of the 104 remaining, 96 had negative induction x-ray films, but 8 had been admitted to the Army, although their initial x-ray films showed small lesions. In another analysis of 328,325 examinations, it was demonstrated that the error in reading films amounted to only 0.003 per cent, since 11 cases of tuberculosis developed in soldiers whose initial x-ray films actually showed lesions but had been interpreted as negative.¹¹ An additional 16 men (0.004 per cent) whose induction x-ray films showed no disease subsequently developed tuberculosis while in the service.

Recognizing that tuberculosis presented a serious threat to the health of the nation, the United States Public Health Service inaugurated its own program shortly after war was declared.^{13, 14} An Office of Tuberculosis Control was established with the following functions and objectives: chest x-ray examination for workers in war industries; chest examination and health education of families in war-industry communities, especially in the underprivileged; chest x-ray examination of Coast Guard recruits; immediate reporting to state and city health departments of men rejected with tuberculosis; and tuberculosis consultation service to state health departments on request.

Two auxiliary projects, of minor importance now but of presumably greater importance in the future, have also been initiated. The first is a routine chest x-ray examination for all admissions to large general hospitals. The second is chest x-ray examination for inmates and employees of state institutions, especially those for mental disease.

To implement this ambitious program, ten portable x-ray units were obtained and set up in trailer automobiles. Each complete unit costs about \$6200 and is staffed with three workers—a physician, a technician and a clerk. Under usual working conditions between three hundred and five hundred photofluorograms (35 mm.) can be taken daily, and the present rate of work for each mobile unit is about two thousand x-ray examinations a week. In co-operation with industry, 250,000 workers were x-rayed in 1942. It is estimated that 1,000,000 examinations will be made in 1943 at a unit cost of 15 cents per examination. Plans for enlarging the program of the Office of Tuberculosis Control did not materialize completely because of failure to obtain an expanded appropriation.

Tuberculosis in industry. Industry has become more cognizant of the role that it can play in eliminating tuberculosis.^{15, 16} In industry it is a combination of several factors that tends to bring about an increase in tuberculosis. The strain of accelerated production under which new workers find themselves causes some breakdowns in those whose lesions are latent or unhealed. Besides, many persons who know they have tuberculosis take the risk to their health and enter industry because of high wages. A third factor is that in the search for employment many persons shift from low-rate tuberculosis areas to areas with high rates, and vice versa. Management has recognized the fact that under wartime stress tuberculosis is likely to increase, but it has been exceedingly difficult to induce labor to establish its own antituberculosis program.

Sawyer,¹⁵ under whose direction the incidence of tuberculosis among employees of the Eastman Kodak Company has been reduced from 2.3 per cent in 1921 to 0.5 per cent in 1941, has presented an "ideal" plan for tuberculosis control: a chest roentgenogram of all present employees; a chest roentgenogram of all applicants for employment; and periodic follow-up roentgenograms of all employees.

Miniature versus regular films. The superiority of x-ray examination over other methods of case finding is admitted by all, but there is still considerable disagreement concerning what procedure is best suited to mass surveys. Excellent reviews of the problem have appeared.¹⁷⁻²² As has been pointed out, the Canadian Army prefers the 14-by-17-inch celluloid film; the United States Army, the 4-by-5-inch or 4-by-10-inch stereo; the United States Navy and Public Health Service, the 35-mm. film. In New York City and elsewhere the 14-by-

17-inch paper film is used routinely. For diagnostic accuracy the 14-by-17-inch celluloid film ranks first, but there is some difference of opinion whether the 14-by-17-inch paper film outranks the 4-by-10-inch stereo. The 35-mm. film is regarded as being on a par with fluoroscopy,¹⁹ but because of its size, it does have some advantages in mass survey work.

Statistical summary. As a result of the almost universal adoption of the chest x-ray examination in both the armed services and industry, it is expected that at least 25,000 new cases requiring hospitalization will have been discovered by the end of 1943.²² Existing sanatorium facilities are pitifully inadequate to absorb the additional load of 25,000 new patients.^{23, 24} Even the most recent statistics⁷ fail to demonstrate the real gravity of the situation because the actual number of available beds in many institutions has been reduced by loss of personnel far below the figures given. Early in 1942 the number of beds for tuberculosis patients in this country totaled 97,726, or 1.62 per death, in 1940 (in 1938 the ratio was 1.41). Minimum standards for hospital facilities require 2 beds per annual death; recommended standards are set at 3. In 1942 only seven states and the District of Columbia met the recommended standards. To care for the burden of the newly discovered cases it is estimated that thirty-two states need from 100 to 6000 additional beds. Massachusetts has a theoretical surplus of 1279 beds above minimum standards to take care of an expected 700 new cases. As has already been indicated, this surplus probably exists only on paper. Many sanatoriums in this state have already been forced by wartime restrictions to reduce the actual number of beds.

TUBERCULOSIS CONTROL IN CIVILIAN LIFE

General hospitals. Recent articles call attention to the fact that the general hospital has not been fully utilized as a source of case finding. In one hospital, routine x-ray examination over a period of eighteen months demonstrated that 4 per cent of the patients had evidence of tuberculous infection and that in 0.6 per cent it was active or questionably active.²⁵

Approaching the problem somewhat differently, Farber and Clark²⁶ analyzed the records of 100 patients consecutively admitted to a general hospital with diagnoses other than tuberculosis and who were later proved to have this disease. Sixty-eight had positive sputums and 3 others discharged tubercle bacilli from extrapulmonary foci. Because of delay or error in diagnosis these patients — a menace to the health of other patients and employees — remained in the hospital a total of 1497 days before transfer to the tuberculosis service. Since 95 of the 100 were pulmonary cases, the value of a routine chest x-ray examination in a general hospital is readily demonstrated.

Nurses and medical students. In view of the fact that unrecognized tuberculosis exists so commonly in hospitals where physicians and nurses receive their training, it is not surprising that it is so serious an occupational hazard for them. The literature pertaining to nurses for the years 1935-1940 has been reviewed by Whitney and Stofer.²⁷ Nurses who spend a portion of their training on a tuberculosis service have a higher infection rate (as measured by the conversion of the tuberculin test from negative to positive) and possibly a higher morbidity rate than those who do not.²⁸ For students of medicine the problem is equally serious.²⁹ Myers and his associates³⁰ compare a group of lawyers with a similar group of physicians and point out that over 7 per cent of the physicians reported having had tuberculosis, whereas less than 2 per cent of the lawyers developed the disease. They show further that since 1936, when a program to protect medical students was adopted, there resulted a gratifying reduction in the number of students infected. Todd³¹ believes: "Annual checking of students and nurses, particularly nurses, is entirely inadequate to properly safeguard health. Tuberculin tests should be made every three or four months and all positive reactors routinely examined by x-ray at the same interval."

Colleges. Lyght³² reports that for the academic year 1940-1941 three hundred and four colleges and universities had tuberculosis programs, an increase of two hundred in four years. There can be no question that in the absence of a definite case-finding program many cases are missed. Lees³³ points out that during 1941-1942 only 11 new cases of tuberculosis were discovered at one hundred and seventy-seven colleges that provided for no case finding (an incidence of 0.07 per 1000 students), in contrast to 744 new cases in three hundred and eleven colleges with such a program (an incidence of 1.3 per 1000). Available reports indicate that the infection rate in colleges has declined 30 per cent.

Extrafamilial contacts. A valuable paper by Twinam and Pope³⁴ calls attention to the fact that failure to find the source of infection within a household should only serve as a stimulus for added search among the extrafamilial contacts.

County accreditation. Hailed as a "new idea in human tuberculosis control," county accreditation applies to human beings some of the technics used in eliminating tuberculosis from cattle. The plan, initiated in Minnesota, consists of awarding certificates to those counties where reasonable success has been obtained in finding and controlling tuberculosis according to established standards. Details are to be found in an article by Myers,³⁵ but briefly the standards require an average death rate of 10 or less per 100,000 population and a tuberculosis infection rate, as evidenced by a positive tuberculin test, of less than 15 per cent among high-school seniors. At least seven of Minnesota's eighty-seven

counties have already been accredited. A worthwhile step has been taken.

Simplified procedures. Case finding is "big business"³⁶ and, as has been pointed out, mass surveys have received great impetus from the war. Because of the increased volume of the work, unproductive tasks must be eliminated. Simplified procedures employed in New York City include, among other things, abbreviated history taking, elimination of routine physical examination and interpretation of x-ray films according to an established code.

CHEMOTHERAPY AND VACCINES

The discovery of the sulfonamides has led to a search for related chemicals that might be of value in the treatment of tuberculosis. The zeal of the bacteriologists hunting for a vaccine is a match for the fervor of the chemists. Chemicals and vaccines have been found—but, although they appear to be of some usefulness in the laboratory, their worth in the clinic must still be demonstrated. Skepticism in the evaluation of experimental research is a sound attitude; cynicism is not.³⁸

Chemotherapy. The sulfones have displaced the sulfonamides in interest.^{39, 40} The in-vitro action of these chemicals in inhibiting growth of tubercle bacilli roughly parallels their therapeutic effects in guinea pigs.³⁸ Up till now promin, the sodium salt of *p, p'*-diaminodiphenylsulfone-*n, n'*-didextrose sulfonate, has been subjected to the greatest amount of study. It is definitely established that promin has a deterrent effect on tuberculosis in guinea pigs,^{41, 42} and even when the experimental tuberculous process has already developed it can be resolved under the influence of this chemical.⁴³ Some guinea pigs, with the aid of promin therapy, develop such a high degree of immunity to tuberculosis that no macroscopic evidence of the disease can be found a year or more after therapy is discontinued.⁴⁴ Inhalation of nebulized promin is said to be even more effective than when the drug is given by mouth.⁴⁵

Human experiments with promin are less encouraging. Given by mouth to 32 patients, the drug was more toxic than for guinea pigs and it appeared incapable of sterilizing the body of tubercle bacilli.⁴⁶ When it was given by the massive intravenous-drip method,⁴⁷ no beneficial effect was observed in 12 patients treated. British investigators⁴⁸ have had some success in treating laryngeal tuberculosis by applying promin locally and believe that further experiments are warranted.

At present other derivatives of diaminodiphenylsulfone are coming under investigation.⁴⁹ Of these, disodium formaldehyde sulfoxylatediaminodiphenylsulfone has been found to be less toxic for guinea pigs^{50, 51} and appears to be of some promise. Research at the National Institute of Health indicates that phosphoryl derivatives should be investigated more thoroughly.⁵²

Vaccines. Vaccination for the prevention of tuberculosis is by no means a new idea.⁵³ The only justification for taking this topic up is that two recent attempts at developing a safe and reliable vaccine appear worthy of mention.

Steenken and Gardner⁵⁴ have used the living avirulent bacterial dissociates of five different strains of tubercle bacilli in an effort to enhance the low resistance of the guinea pig to tuberculosis. They found that the immunity of guinea pigs, as determined by the subsequent inoculation of a virulent strain, could be increased. They believe that they have obtained proof that the avirulent dissociate is not devoid of antigenic properties and that immunity may not be type specific.

Potter^{55, 56} has approached the vaccine problem somewhat differently. He noted that whereas tubercle bacilli may remain alive for two or more years under high vacuum when stored dry, they are readily killed at body temperature in the absence of oxygen if sufficient moisture is present. His technic is to give the tubercle bacillus an environment where its metabolic needs are high and at the same time deprive it of an essential constituent—oxygen. In this way Potter demonstrated that tubercle bacilli gradually die off and that all the bacilli are dead after one month's incubation in the moist state at 38° C. and under a high vacuum. By this method an avian strain (P₄) was prepared as a vaccine, and the virulent organism itself was used for subsequent tests in rabbits. A greater degree of immunity was conferred on the experimental animals than had been obtained with any of the earlier vaccines used. But since the immunity was incomplete, other studies are now in progress to improve the method of vaccination.

SURGERY

Current trends in collapse therapy have been analyzed by Drolet.⁵⁷ Summarizing a five-year (1937-1941) survey of one hundred and one Canadian and American hospitals with a total bed capacity of 33,050, he found that about 50 per cent of all patients were given some form of collapse treatment. Apparently the number of patients receiving artificial pneumothorax was stabilized during this period, but the number of phrenic nerve operations decreased 8 per cent. On the other hand, there was a 34 per cent increase in the number of intrapleural pneumolyses. About 4 per cent of the patients in sanatoriums were subjected to thoracoplasty in 1941 and, compared with 1934, there was a four-fold increase in the number of patients who had this operation. In the New England states the ratio of patients subjected to thoracoplasty has increased from 56 to 89 per each 1000 patients. But, as Davidson⁵⁸ and Churchill and Klopstock⁵⁹ point out, analysis of current trends has but a limited usefulness as a guide to therapy in a field as rapidly advancing as thoracic surgery.

The treatment of pulmonary tuberculosis complicated by tracheobronchial disease is a specific problem that continues to be the subject of considerable debate. Myerson,⁶⁰ who believes that tuberculosis of the bronchus and trachea has a good prognosis, regards pneumothorax as "superfluous once a bronchial lesion develops." Salkin and his co-workers,⁶¹ on the other hand, favor the use of collapse treatment except in cases complicated by bronchial stenosis. Their conclusion is, "Some of our best results of bronchitis have followed the use of pneumothorax and thoracoplasty." Unfortunately by placing in one category those cases treated by pneumothorax and those treated by thoracoplasty, these authors have evaded one of the most controversial aspects of the entire problem. Both procedures—pneumothorax and thoracoplasty—must be analyzed independently if there is to be any clarification of the disputed issues.

Considerable light was thrown on the subject of tracheobronchial tuberculosis in a recent symposium.⁶²⁻⁶⁴ The consensus is that the presence of tuberculous bronchitis greatly complicates the treatment of the pulmonary lesions. Pneumothorax gives poor results and, when it is ineffective, it is worse than "superfluous," for it encourages complications, such as empyema and unexpanded lung. In cases of definite stenosis, neither pneumothorax nor phrenic nerve operations are as effective as thoracoplasty. The advantages of thoracoplasty can be summed up as follows: it is the safest procedure, atelectasis seldom results, infection of the pleural space is rare, and late suppurative changes within the lung are prevented.

According to Rafferty and Shields⁶⁵ pneumothorax is to be condemned in the presence of bronchial stenosis, for it causes interference with bronchial drainage and encourages atelectasis. They advocate the following plan of management when bronchial disease is discovered: attention should be centered mainly on the bronchus rather than on the pulmonary lesion; the idea of collapse treatment should be abandoned, at least temporarily; early treatment should consist of a longer than average trial of bed rest; artificial pneumothorax may be cautiously attempted if the bronchial disease appears to be slight; and thoracoplasty, in most cases, is preferable to pneumothorax.

From a purely theoretical standpoint lobectomy and pneumonectomy may be the procedures of choice when stenosis complicates the usual forms of treatment. That resection of a lung is practical as well as theoretical is being borne out by a gradually accumulating mass of evidence. In a group of 12 cases reported by Benedict,⁶⁶ one lobectomy and three pneumonectomies were done. Of the pneumonectomies, one was done after an unsuccessful thoracoplasty. There was only one death, and that was due to subsequent extension of the disease in the contralateral lung. Behrend⁶⁷ points out that

pneumonectomy should be limited to those cases in which there is chronic ulcerative tuberculosis of the bronchus with ipsilateral pulmonary disease.

The number of lobectomies done for tuberculosis is gradually increasing. Drollet⁶⁷ reports that there were only 9 done in 1937 but 14 in 1938, 16 in 1939, 25 in 1940 and 28 in 1941. The rationale for lobectomy is clearly outlined by Churchill and Klopstock.⁶⁹ Lobectomy and pneumonectomy are procedures distinctly different from one another, each with its own set of indications. Pneumonectomy is not an alternative to collapse therapy since it is both irreversible and nonselective. On the contrary, lobectomy is highly selective and is more conservative of pulmonary function than a seven-rib thoracoplasty. A lobectomy may be considered as an alternative to artificial pneumothorax when there has been irreparable destruction of lung substance. Lobectomy shortens the span of treatment, maintains (better than thoracoplasty) the integrity of the thoracic cage, and removes the offending lesion. If, after bed rest and pneumothorax treatment, "there is good reason to believe that the therapeutic goal of a re-expanded lung, with a closed lesion, cannot be achieved within a reasonable length of time, lobectomy may be considered."

MINOR NOTES

Pregnancy. Although pregnancy is an added burden to a woman with tuberculosis, the current trend is toward less interference with the pregnancy and more treatment of the tuberculosis. Interruption of pregnancy is being advocated less and less.⁶⁸

Two recent papers are especially deserving of mention. One report concerns a group of 86 women, eighteen to thirty-nine years of age, whose pregnancy was allowed to go to full term.⁶⁹ Of these, adequate follow-up on 82 revealed that only 15 (18 per cent) were dead, in contrast to 39 per cent deaths for all women of the same age group discharged from the sanatorium for the first time during the same period (1921-1940). No explanation is advanced for the puzzling statistical conclusion that the death rate of all women between the ages of eighteen and thirty-nine is double that of the pregnant group. The authors remark conservatively that "while this group is too small to warrant definite conclusions . . . it seems to indicate that when tuberculosis is properly treated pregnancy probably does not adversely affect the tuberculous process."

The second paper is that of Lyman,⁷⁰ who made an intensive study of 1818 women discharged from the Gaylord Farm Sanatorium. In order to determine the effect of marriage and pregnancy on the course of the disease he divided his patients into three groups—single, married and later married. Follow-up studies revealed that of 782 married women 41 per cent were dead and that of the 721 single women 51 per cent were dead.

prisingly, there were only 40 deaths (13 per cent) of the 315 later married. In this group, if reactivation of the disease occurred at all, it did so without exception during pregnancy or within three months post partum. In the light of Lyman's statistics, advice against marriage to a young woman with arrested tuberculosis appears, on the whole, unjustifiable.

The need for the routine inclusion of chest x-ray examination in prenatal clinics and lying-in hospitals cannot be urged too strongly. Recent evidence proves that ten times as many cases of active tuberculosis can be found in those hospitals where routine x-ray screening is done than in those hospitals where no such program exists.⁷¹

Anatomy of the tubercle bacillus. The electron microscope has helped to elucidate some of the controversial details concerning the structure of the tubercle bacillus, since it allows for full resolution of an object at magnifications up to 100,000. One disputed point—the question of the capsule—has been settled. Electron photographs show that a membrane or capsule is uniformly present and that in some instances it contains granules.⁷²

New technics. By the use of fluorescent microscopy tubercle bacilli can be demonstrated with greater rapidity and with a greater number of positive tests than by the use of ordinary staining technics.⁷³

The chorioallantoic membrane of the chick embryo can be made to serve as a reliable rapid culture medium for the differentiation of tubercle bacilli, especially regarding degrees of virulence. Within six days after implantation of suspensions of bacilli, 96 per cent tubercle formation was present in the membranes implanted with a virulent strain, in contrast to only 18 per cent tubercle formation in those implanted with a closely related but avirulent strain.⁷⁴

Serum albumin and globulin, as determined by electrophoresis methods, show changes that parallel the clinical course of tuberculosis, both in experimental animals and in human beings.⁷⁵

Ascoli,⁷⁶ in transplantation experiments on calves, has brought forth evidence to show that presence of an active tuberculous nodule enhances resistance to tuberculosis. Further work along the lines suggested by his research should be of considerable interest.

CASE 30021

PRESENTATION OF CASE

First admission. A seventy-year-old retired dentist entered the hospital because of swelling of the legs.

The patient had been in excellent health until the age of sixty-five, at which time he had several episodes of hemoptysis. Sputum examination and x-ray films of the chest were positive for tuberculosis. He spent thirteen weeks in a sanatorium, and was sent home without any further signs or symptoms. From that time on he had been bothered by "gas in the stomach."

About six months before admission the patient noticed the insidious onset of edema of the lower extremities, which progressed and extended up to the midcalf. This was associated with a sense of uneasiness and tiredness in the legs, but there was no pain, and no dyspnea or orthopnea. He had lost about 9 pounds but believed that this was due to the change in his life consequent to his wife's death.

Physical examination showed a well-developed, poorly nourished man, with sacral edema. The thoracic wall was deformed, the sternum being thrust anteriorly and rotating to the right. The cardiac border could not be made out, but the sounds were of good quality and regular. There was slightly diminished resonance throughout the right lung, but no rales were heard anywhere.

The blood pressure was 190 systolic, 100 diastolic. The temperature was 98.6°F., the pulse 72, and the respirations 20.

Examination of the blood showed a red-cell count of 3,880,000, with a hemoglobin of 12.2 gm. per 100 cc. The white-cell count was 18,200, with 86 per cent neutrophils. Urine examination showed a specific gravity of 1.015, a + test for albumin, and rare red and white cells. A blood Hinton test was negative. The blood sugar was 61 mg. per 100 cc., the nonprotein nitrogen 32 mg. A phenolsulfonephthalein test gave 20 per cent excretion in fifteen minutes, with a total of 60 per cent at the end of two hours.

X-ray examination of the chest showed a hazy and linear density throughout the right upper lung

*On leave of absence.

field. Linear, sharply defined areas of increased density were seen throughout both midlung fields. The diaphragm was low in position, with limited expiratory motion. A Graham test was negative. A gastrointestinal series was noncontributory. An electrocardiogram showed normal rhythm, a rate of 70 and slight slurring of R₂. The ST segments in Leads 1, 2 and 4 were slightly concave, suggesting digitalis effect. The T waves were low throughout. There was sinus arrhythmia. The patient was discharged at the end of six days with a diagnosis of nutritional edema.

Second admission (three months later). After discharge, the patient placed himself on a regime of essence of peppermint, sodium bicarbonate and luminal, with considerable relief of his stomach distention. He also took 1½ gr. of digitalis daily. The swelling of the legs increased and involved the thighs and hips. During the week before admission he noted decrease in acuity of close vision, dullness of his sensorium and a general feeling of inadequacy. There had been considerable itching of the skin and some gain in weight.

Physical examination showed marked boggy an pitting edema, extending up to the lower border of the scapulas. There was some scrotal edema. Scattered, fine, crackling rales were heard over the upper right chest anteriorly and posteriorly, with dullness in the right upper chest anteriorly. The examination was otherwise the same as previously.

The blood showed a red-cell count of 4,060,000 and a white-cell count of 7700, with 65 per cent neutrophils. The urine had a specific gravity of 1.014 but was otherwise negative. The nonprotein nitrogen was 30 mg. per 100 cc., and the blood protein 6.3 gm., with 4.0 gm. of albumin and 2.3 gm. of globulin — an albumin-globulin ratio of 1.7.

The patient continued to take digitalis daily. On the third hospital day he was given 1 cc. of Mercupurin intravenously. His urinary output was between 1750 and 1250 cc. on an intake of about 1400 cc. daily. A phenolsulfonephthalein test on the fourth hospital day gave 10 per cent excretion in fifteen minutes, and a total of 40 per cent at the end of two hours. The nonprotein nitrogen was normal. On the fifth hospital day the urine showed a +++ test for albumin and contained many red cells which persisted for almost three weeks. During the second week the temperature ranged between 100°F. and 102°F.; the pulse was about 80, and the respirations 25. Cultures of the blood and urine were negative. An intravenous pyelogram performed on the tenth hospital day showed a normal outline of the left kidney. Several calcified nodes were seen overlying the left kidney. The kidney and pyelographic outlines on the right were not visualized. Intravenous dye appeared promptly on the left side. The left calyces and pelvis were incompletely visualized but were not grossly abnormal. The right calyx

were not well seen. The right lower calyx was enlarged and deformed. The examination was not entirely satisfactory. A cystoscopy on the twentieth day revealed bloody urine in the bladder, from which a handful of clot was removed. There was slight trabeculation; both ureteral orifices were normal, and clear urine was seen coming from both. The prostate was enlarged, but no masses could be felt in the pelvis. A retrograde pyelogram showed the right superior and inferior calyces to be separated, and there was a questionable filling defect. One of the right middle calyces was somewhat blunted, and the kidney appeared enlarged. The left kidney and pelvis were normal.

The patient was given one transfusion of blood and received a high-calorie, high-vitamin diet. His condition improved considerably after the first three weeks; the hematuria subsided, the edema disappeared, and he was discharged eight weeks after admission.

Third admission (two months later). The patient had felt well for the first four weeks and then developed a dull aching pain in the right flank, which became progressively severer. Standing seemed to aggravate it. He had nocturia four or five times but no other urinary symptoms. During the ten days prior to admission he had two attacks of vomiting. In the second one, the material was described as "catsup colored." He had swelling of the legs on two occasions. He thought that he had lost about 6 pounds during this period.

Physical examination showed soft pitting edema of both ankles, with scaling of the skin. The lungs were clear. The heart was of normal size. The sounds were regular and of good quality. There was an occasional dropped beat. A rather firm, movable, tender mass was palpated in the right flank, which shifted slightly, if at all, with respiration. The mass was the size of a grapefruit, and its upper border disappeared under the costal margin. Many dilated veins extended over the abdomen to the lower thorax.

The blood pressure was 100 systolic, 40 diastolic. The temperature was 98°F., the pulse 80, and the respirations 20.

Examination of the blood showed a red-cell count of 3,510,000, with a hemoglobin of 70 per cent. The white-cell count was 9600, with 71 per cent neutrophils. The urine showed a + test for albumin and occasional red and white cells; the specific gravity was 1.018. The blood sugar was 111 mg. per 100 cc., and the nonprotein nitrogen 34 mg. The blood chloride was 99.9 milliequiv. per liter, and the carbon dioxide combining power 22.5 millimols per liter. The blood protein was 7.2 gm. per 100 cc. Two cultures of the urine were negative; one showed moderate numbers of nonhemolytic streptococci, two showed *Staphylococcus albus*, and one showed colon bacilli and enterococci.

Retrograde pyelograms failed to define the outline of the right kidney accurately, but it appeared to be

enlarged. There was upward displacement of the upper part of the ureter, without lateral displacement. All the calyces were somewhat enlarged, irregular and blunt. There was considerable anterior displacement of the right ureter. Several non-opaque filling defects were seen in the calyces, which were interpreted as stones or blood clots. X-ray films of the chest taken about eight months after the first films showed progression of the process, especially in the base and the lateral aspect of the left lung field. The process consisted of flecky and streaky areas of increased density in the central and lateral lung fields. Several areas of increased density were apparent in the region of the left base, as well as a triangular dense shadow close to the right hilus.

The patient was discharged at the end of the fourth week without apparent change in his condition.

Final admission (four months later). For about two months the patient remained the same. An x-ray film of the chest during this period showed further progression of the pulmonary process. The lesions had a more sharply outlined and nodular appearance than formerly. He developed progressive shortness of breath and cough. The abdomen increased in size. Breathing became progressively more difficult.

Physical examination showed a pale, emaciated man in marked respiratory distress. There was dullness anteriorly over the right lower lobe, with decreased breath sounds and definite egophony. Scattered rales were heard over both lower lobes. The abdomen was grossly distended, and there were many large and prominent veins.

The blood showed a red-cell count of 3,820,000, with 10.7 gm. of hemoglobin. The white-cell count was 6600, with 76 per cent neutrophils. The urine was negative. An abdominal paracentesis yielded 5000 cc. of greenish fluid, with a specific gravity of 1.016 and a protein content of 2.2 gm. per 100 cc. Following the tap, there was marked relief of the respiratory distress, and a large, firm, nodular mass was palpable in the right upper quadrant. X-ray studies of the chest showed questionable fluid in the right pleural cavity.

The patient's condition gradually became worse, and he died on the tenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JOSEPH C. AUB: May we see the x-ray films?

DR. LAURENCE L. ROBBINS: The gastrointestinal films simply show anomaly in position. So far as the chest is concerned, I believe that there is definite evidence of tuberculosis in the right apex. There is something more, however — a diffuse linear process involving both lungs. These films were taken at the time of the original admission. After an interval of about eight months, the appearance of the chest changed considerably. In addition to what was previously present, there are now definitely round

shadows. These shadows I believe are superimposed on the other process. This shadow here is what raised the question of fluid, and I should think that it is perfectly consistent with fluid in the right pleural cavity.

So far as the intravenous pyelograms are concerned the majority of films were unsatisfactory. This retrograde pyelogram was done eight months after the first admission and is the one from which most information was obtained. Of greatest significance is the fact that the lower pole of the kidney is obscured and not seen, but I cannot visualize a definite mass. There is elongation of the two lower calyces, with displacement of the ureter forward.

DR. AUB: In the diagnoses we must place an old one — pulmonary tuberculosis — and sclerosis of the aorta, because of hypertension and a distortion

vena cava in a progressive manner. The normal blood protein of 6.3 gm. also fits in with the idea that obstruction may have been the cause of the edema. The next diagnosis that one has to make is a retroperitoneal tumor mass in the region of the right kidney. It may have originated from the kidney or from the adrenal gland, or it may have been a primary retroperitoneal tumor. I think that one must arrive at the conclusion that the mass was a metastasizing neoplasm, since the masses shown in the x-ray film of the chest are suggestive, although not typical, of metastatic neoplasm rather than of tuberculosis. The only other diagnosis I can make is tuberculosis of the kidney. The patient had hemorrhage from the kidneys, which suggests tuberculosis, and we know that he had pulmonary tuberculosis. If it were tuberculosis of the kidney, I should ex-

FIGURE 1. Renal-Cell Carcinoma of Right Kidney with Extension into Both Renal Veins and Inferior Vena Cava.

of the chest, with change in the position of the heart. Incidentally, this man was seventy years old and I have no desire to make a single diagnosis. The older the patient, the more diagnoses he rates.

Then we come to the mass in the abdomen, which may have several interpretations. The stomach was displaced, which Dr. Robbins says was a congenital anomaly; but it also might have been due to the mass displacing it. From the beginning there was evidence of obstruction to the vena cava. First there was edema, then increased venous flow in the abdominal wall with many superficial veins; so whatever was present in the abdomen obstructed the

pect, but not insist, that there would have been evidence of tuberculosis in the bladder. The only suggestion of anything wrong with the bladder is the slight trabeculation. Extrarenal tumors are of various types — sarcomas, neurofibromas, fibromas, adrenal-rest tumors and cysts; but none of these appeal to me because the lesion is obviously in the kidney, particularly in the calyces, pushing the ureter forward and obstructing it. Does this film suggest obstruction?

DR. ROBBINS: I do not believe that there is much obstruction by the process; the ureter is displaced forward.

DR. AUB: So we come to the diagnosis of the type of neoplasm of the kidney. Now, I leave an area of relative security and plunge into a less secure one. This may have been a hypernephroma in which there was a hemorrhage, as evidenced by bleeding. If it were a hypernephroma I should expect to have seen more definite snowball-like lesions in the x-ray films of the chest. Somehow I rather suspect that this lesion was more in the hilar region of the kidney, and when tumors are primarily located there they are usually papillary epitheliomas. That is the diagnosis which I think is more likely to be made, although these tumors are less frequent than the hypernephromas. I believe that it broke through, grew outside the kidney and pushed the ureter to an anterior position, with a good deal of growth behind the kidney. From the description the ureter was probably involved, although I do not believe that I can make that diagnosis from these x-ray films. It also produced obstruction of the vena cava and pushed the duodenum over. These tumors may also have pulmonary and bone metastases. I do not believe that this was renal tuberculosis.

The patient was discharged eight weeks after the second admission. Why they did not operate then I do not know, but I suspect that it was because of the x-ray films of the lungs.

DR. FLETCHER H. COLBY: I saw the patient during his second admission. It is not quite clear from the history that the patient was in a critical condition even at that time. When it was considered whether to cystoscope the patient, Dr. Dwight Siscoe wrote in the record, "It might be considered unwise by some to put him through a retrograde pyelogram but to me it seems to be either that or just sitting back and waiting until he dies." In other words, the patient was in extremely poor condition even as early as the second admission. At that time there were dilated veins in the abdominal wall. We suspected that the bleeding, which was gross and copious, might have been due to the Mercupurin. It seemed to me, however, that there was probably some other cause, such as a bladder tumor. The patient was cystoscoped, and the bladder was normal except for some trabeculation, which is evidence of mild obstruction rather than of tuberculosis. At the time of discharge it was thought that the patient probably had a malignant tumor of the right kidney, with obstruction to the vena cava. The question of operation was never seriously raised because he was in such poor shape and because operation offered him nothing. It is interesting that he had 4600 units of radiation with the 200-kilovolt machine during the last admission and temporarily improved a great deal.

CLINICAL DIAGNOSIS

Retroperitoneal tumor.

DR. AUB'S DIAGNOSES

Papillary epithelioma of pelvis of right kidney, with extension producing obstruction of the vena cava and with metastases to lungs.
Pulmonary tuberculosis.
Sclerosis of aorta.

ANATOMICAL DIAGNOSES

Renal-cell carcinoma of right kidney, with extension into both renal veins and the inferior vena cava and with metastases to lungs, liver and right adrenal gland.
Pulmonary tuberculosis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: From this photograph (Fig. 1) you can see that the right kidney was replaced for the most part by a large tumor, but the most striking thing was this large mass between the two kidneys. The inferior vena cava measured 6 cm. in diameter and was filled with tumor thrombus. This tumor extended into the right renal vein, which was practically obliterated and shortened by the tumor, and then into the vena cava. Other interesting findings were that the left renal vein contained two movable tumor thrombi and that there were metastases to the left kidney. The right adrenal gland was completely replaced by tumor. This tumor thrombus in the vena cava had extended down into both iliac veins and had produced partial obstruction.

The tumor was a hypernephroma or what we prefer to call renal-cell carcinoma. The tumors of the renal pelvis are usually papillary tumors that extend down the ureter. I have never seen one invade the renal vein or extend into the vena cava. The renal tumor that usually invades the vena cava is the renal-cell carcinoma which arises from the parenchyma; the other tumors that are prone to do that are the hepatomas and the carcinomas of the adrenal cortex. The lungs showed numerous metastases as well as active tuberculosis. It is interesting that the tumor thrombus in the inferior vena cava extended up to the liver and also into the hepatic veins and had produced metastases to the liver.

DR. AUB: How about the bones?

DR. CASTLEMAN: They contained no metastases.

CASE 30022

PRESENTATION OF CASE

A seventy-two-year-old white widowed domestic entered the hospital because of swelling of the abdomen and legs of four weeks' duration.

The patient was well until about four to five weeks before admission, when she noted the onset of swelling of the abdomen and ankles. At about the same time she developed a cough and a slight . . . There were oliguria and darkening . . .

She experienced loss of strength and appetite, dyspnea on exertion and easy fatigability. She had had no pain, change in bowel habits, dysuria, nausea, vomiting, hematemesis or jaundice. She was not certain whether she had recently had one or two clay-colored stools.

Fourteen years before admission the patient had a secondary syphilitic rash, with a positive dark-field examination for spirochetes. She was treated for two years, and the blood became seronegative after the first eight months.

Physical examination showed a poorly nourished, thin woman in no discomfort. The skin was slightly icteric, with numerous superficial varicosities of the legs and occasional varices of the lower abdomen. There was soft pitting edema of both legs to the knees. A few fine crackles were heard at the left base. No definite cardiac enlargement could be made out. There was a moderately harsh, blowing precordial systolic murmur, heard best in the pulmonary and parasternal areas. The sounds were regular and of good quality. The abdomen was protuberant, with a fluid wave and shifting dullness. The liver was percussed two fingerbreadths below the costal margin; it was not palpable. One examiner thought there was a large mass rising from the pelvis to the umbilicus and attached to the uterus.

The blood pressure was 138 systolic, 80 diastolic. The temperature was 98.6°F., the pulse 80, and the respirations 18.

Examination of the blood showed a red-cell count of 4,470,000, with 11 gm. of hemoglobin. The white-cell count was 11,000, with 80 per cent neutrophils. A blood Hinton test was negative. The urine had a specific gravity of 1.026 and gave a + test for bile; the sediment of a catheterized specimen contained 5 to 15 white cells and 15 to 20 red cells per high-power field. The stools were yellow, watery and guaiac negative. The nonprotein nitrogen was 20 mg. per 100 cc., and the protein 5 gm. The direct van den Bergh was 1.8 mg. per 100 cc., the indirect 2.5 mg. The prothrombin time was 29 seconds (normal, 16 seconds). The hematocrit was 44.5. A cephalin flocculation test was ++ in twenty-four hours and +++ in forty-eight hours.

An intravenous pyelogram was negative. On x-ray examination there was a large, soft-tissue mass, probably an enlarged uterus, filling almost the entire pelvis and pressing on the roof of the bladder. A gastrointestinal series and a barium enema were negative except for the presence of fluid in the peritoneal cavity. No esophageal varices were seen. X-ray films of the chest showed some linear areas of atelectasis at both bases, probably due to abdominal ascites. The lung fields were otherwise clear. The heart was transverse in position but not greatly enlarged.

The patient's condition improved slightly during the first week. The urine cleared almost completely, and there was no bile. Abdominal paracentesis on

the sixth day yielded 6 liters of clear, straw-colored fluid; no tumor cells were seen. Peritoneoscopy showed a large, round, rather hard, white mass, approximately 15 cm. in diameter, in the pelvis. The liver edge was irregular and nubby but of normal color. There was no evidence of tumor metastases.

Although there was a moderate degree of drainage through the peritoneoscopy incision, the fluid seemed to reaccumulate in the next four to five days. On the fifteenth hospital day the patient became drowsy and irresponsive. She was given daily intravenous fluids with vitamins. The prothrombin time was 30 seconds (normal, 20 seconds). The hematocrit was 39.7, and the nonprotein nitrogen 18 mg. per 100 cc. The blood chloride was 105.5 milliequiv. per liter, and the carbon dioxide combining power 20.4 millimols per liter. The following day the patient became comatose. Examination was essentially as before, except for a fetid, somewhat mousy breath and hyperactive tendon reflexes and knee jerks. The urine gave a + test for albumin and a ++ test for bile, and contained innumerable white cells. A culture gave many colonies of colon bacilli. The nonprotein nitrogen, however, was only 16 mg. per 100 cc. She remained in coma and died on the twenty-fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS D. MOORE: This is the story of a previously well seventy-two-year-old woman who over a four-week period, developed evidence of obstruction of the portal vein and of the veins of the legs, became acutely ill, passed into coma with jaundice, and died. To this train of events we have added a pelvic tumor and some evidence of infection of the urinary tract. The relation of the latter two to the main train of events is not too clear. The patient's story suggests the gradual onset of a systemic disease, probably due to visceral damage, with few localizing symptoms but with loss of weight, strength and appetite, dyspnea and fatigability. The only localizing factor that we have is the questionable story of clay-colored stools and the development of jaundice.

The fact that fourteen years ago she had a secondary syphilitic lesion may have some bearing on the present trouble. The treatment, however, sounds adequate. She became seronegative at that time and on admission had a negative Hinton test, so for the moment I shall disregard syphilis.

On entry the skin showed superficial varices of the legs and lower abdomen, which may have been the telangiectatic type of varices that one sometimes sees in parenchymatous disease of the liver. The edema seemed to be confined to the legs. No cardiac enlargement could be made out, and this, together with the x-ray findings, the other physical findings and the essentially normal blood pressure, tends to rule out heart disease as the fundamental lesion. Another

sion that in a person of this age could well be of great importance is chronic pyelonephritis. She had red and white cells in the urine, as well as albumin. Since the urine concentrated, however, to 1.026 and since she never showed an elevation of the non-protein nitrogen I think it is best to regard these urinary findings as due to a colon-bacillus cystitis, probably associated with the pelvic tumor, which was pressing on the bladder and probably altering its function.

The physical findings pertaining to the liver are highly significant. She was slightly icteric, she had fluid wave, and the liver was apparently enlarged. Along with this, there was bile in the urine and a van Bergh of 2.5 mg. indirect and 1.8 mg. direct. A proportion of direct to indirect bilirubin of less than 1 per cent is strongly against an extrahepatic cause for jaundice. In other words, obstruction of the common bile duct usually produces a percentage of direct to indirect bilirubin that is 75 per cent or higher. The range of this proportion does not definitely indicate parenchymatous liver disease as its source but it certainly is strongly suggestive. Low percentages of direct to indirect bilirubin are usually associated with hemolytic processes. We have no evidence for that here, as the red-cell count was in the normal range.

The prothrombin time was almost twice the normal, which certainly is also suggestive of liver disease. Furthermore, we see later that she received daily intravenous infusions with vitamins and that the prothrombin time became 30 seconds, with a normal of 20 seconds. Owing to the facts that most intravenous vitamin mixtures used in this hospital at the present time contain vitamin K or one of its precursors and that after receiving these vitamins intravenously she still had an elevated prothrombin time, we have here further excellent evidence that this patient had severe liver damage. As a matter of fact, the response of the prothrombin time to parenterally administered vitamin K is an excellent index of liver function, and this patient apparently showed no response at all. Fitting in with this concept is the cephalin flocculation test, which was +++ in forty-eight hours. The finding of 6 liters of clear straw-colored fluid in the abdomen is simply a part of this picture, the result presumably of portal obstruction. The serum protein of 5.0 gm. per 100 cc. is probably also an expression of hepatic failure, and the edema in the legs could have been due to this factor, although we do not necessarily see peripheral edema with a serum protein of 5.0 gm. She had a pelvic tumor, however, and with a local fault to aggravate the situation, edema progresses rapidly.

Peritoneoscopy showed a liver edge that was irregular and nubby but of normal color and there was no evidence of tumor metastases. This, I think, fits in perfectly with the concept that we are dealing here with diffuse liver damage, such as portal cir-

rhosis or possibly the end results of an earlier subacute hepatitis.

The peritoneoscopy also showed a 15-cm., white, round, large, hard tumor in the pelvis. We have no way of knowing whether it was connected with the uterus or with the ovaries or whether it had nothing at all to do with the reproductive organs. The patient was seventy-two years old and this makes any intrauterine lesion except an endometrial adenocarcinoma extremely unlikely, and yet for an adenocarcinoma of the endometrium to present a large, round, white mass in the pelvis would be most exceptional. Tumors of the ovary, however, frequently give this picture. In a woman of this age most of the common benign and malignant tumors of the ovary may be found. The surface of this tumor was not papillary and there were no implants on the liver or the peritoneum, and no tumor cells in the abdominal fluid, which makes papillary or pseudomucinous cystadenocarcinoma of the ovary moderately unlikely. It could be a large fibroma of the ovary, and with the abdominal fluid, one might think that the fibroma was responsible for the abdominal fluid. We find that she has no fluid in her chest, however, and although this does not rule out fibroma of the ovary, it makes it less likely as a cause for the tremendous amount of abdominal fluid. Other ovarian tumors, including carcinoma of the ovary, can give tremendous amounts of abdominal fluid and even chest fluid without implants and without tumor cells in the fluid. The mechanism of fluid collection in such cases must be in some way related to that in the fibroma group. Therefore, we cannot say with certainty that the ovarian tumor in this woman was not responsible for the fluid collection. But with so much evidence of liver damage, I should think that the ovarian tumor was an incidental and secondary finding, so far as the general trend of this woman's disease and her death are concerned.

After she had been in the hospital for a time, she became comatose and developed a somewhat mousy breath and changes in her reflexes. The mousy breath is classically supposed to be an accompaniment of terminal liver damage. One wonders if this could be due to abnormal circulating amounts of acetamide and related compounds, which, in the purified state, smell like mouse feces.

I am unable to interpret the reflex changes. They could possibly be associated with cerebral thrombosis, a not uncommon terminal event in people of this age, no matter what the underlying pathologic process that is responsible for the depleted condition.

We therefore come down to the diagnosis of liver failure. Owing to the fact that she had massive ascites before the appearance of much jaundice, I think that she had portal cirrhosis rather than biliary cirrhosis associated with either cholangitis or obstruction of the bile ducts. The fundamental etiology for a portal cirrhosis is not clear from the

history. No mention is made of alcoholic intake, and there is nothing to suggest that she had sub-acute hepatitis in the past due to toxins other than alcohol.

Did she have a hepar lobatum? This is a late anatomic lesion due to tertiary syphilis in the liver, and in so far as it is an irreversible pathologic change, it can exist in the presence of a negative serologic test. The peritoneoscopic picture, however, was not that of hepar lobatum, and I should not expect that a patient would have liver failure of this degree on the basis of a hepar lobatum.

I am considering the ovarian tumor to be incidental because the only way in which it could produce this picture would be by liver metastases, for which we have no evidence. I shall make the reservation, however, that the ovarian tumor could have had something to do with the collection of fluid both in the abdomen and in the subcutaneous tissues of the legs. The likeliest solid, round, hard, white tumor of the ovary in a woman of this age is probably a solid or solid and cystic carcinoma. This can occur without papillary projections, and it probably is what she had. Fibroma or cyst is a second bet.

I believe that the patient's death was due to liver failure on the basis of portal cirrhosis, possibly associated with a terminal cerebral thrombosis.

CLINICAL DIAGNOSES

Acute hepatic insufficiency.

Icterus.

Ascites.

Ovarian cyst.

DR. MOORE'S DIAGNOSES

Portal cirrhosis of liver.

Ascites.

Icterus.

Carcinoma of ovary.

ANATOMICAL DIAGNOSES

Toxic cirrhosis of liver, with superimposed acute hepatitis.

Thrombosis of portal and splenic veins, recent.

Splenomegaly.

Ascites, slight.

Icterus.

Cystoma of left ovary.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy showed a small liver that weighed only 950 gm. It was extremely cirrhotic, and the nodules of regenerated liver tissue varied from 0.3 to 1.0 cm. in diameter. This wide variation in the size of the nodules rules out the alcoholic type of portal cirrhosis and is characteristic of the healed atrophy or toxic type. What the toxic agent was remains unknown; but it is quite possible that in the antisiphilic treatment twelve years previously an arsenical was used that was the cause of the liver damage. Microscopically there was evidence of a superimposed acute hepatitis. Recent thrombi were present in the distal portion of the splenic vein and in the main portal vein. The spleen was about twice the normal size, and varices were present in the esophagus. At the time of the autopsy there was only about 100 cc. of bile-stained ascitic fluid.

The pelvic mass proved to be an innocuous simple ovarian cyst, measuring 12 cm. in diameter, on the left side. The brain showed diffuse nerve-cell degeneration of a terminal nature; there was no thrombosis. We found no evidence of syphilis anywhere.

MILITARY MEDICINE

Now that about 90 per cent of all residents, interns and medical students are either medical officers on inactive duty or enlisted men in the Army and Navy and are on an accelerated schedule, one cannot help but wonder how efficiently they are being taught regarding military medicine—that extremely specialized branch of medical practice in which all of them, sooner or later, will be involved.

The problems that confront the medical officer are, by and large, quite different from those that are ordinarily encountered in civilian practice. Of primary importance are the infections and parasitic diseases so prevalent in tropical and subtropical

regions but relatively unheard of in temperate zones. Preventive medicine and sanitation assume most significant roles, and then comes the fact that the methods of medical and surgical treatment in combat zones are, of necessity, entirely different from those in civilian communities. And added to all this are the constant advances that are being made as the result of directed research or of experience, which rarely, if ever, are brought to the attention of the future medical officer and of which even the majority of their instructors are ignorant.

Undoubtedly the Government, at the moment, has no intention of changing the curriculums of medical schools. On the other hand, it seems reasonable that schools and teaching hospitals could turn out men who would have a more thorough and exact knowledge of the military aspects of medicine than they do at present and that this could be done with slight inconvenience and with little change in the methods of teaching that are considered to be basic to all forms of medical practice.

Prior to the present war, only a few of the medical schools in this country had departments of tropical medicine. Within the past two years, the schools lacking such facilities have been given the opportunity of sending members of their teaching staffs to take the regular two-month course in tropical medicine at the Army Medical School in Washington, the expenses having been met by a philanthropic organization. In addition, many of the schools have increased their instruction in preventive medicine and sanitation. Thus, it seems likely that the majority of schools have voluntarily revised their curriculums to cover, more or less satisfactorily, certain subjects that are of utmost importance to the medical officer. On the other hand, it seems extremely unlikely that instruction in medicine, surgery and the various specialties in the schools and teaching hospitals is conducted with the proper emphasis on military needs, largely owing to ignorance of the instructors regarding military medicine in general and recent advances in particular.

There appear to be two ways in which this state of affairs can be improved. In the first place, members of the teaching staffs should be thoroughly cognizant of the military aspects of their specialty and should advise their students to refer frequently

to military manuals, such as those published by the War Department and those sponsored by the National Research Council. Secondly, pertinent directives and monthly bulletins issued by the Army and Navy to their medical officers on active duty should also be forwarded to the commissioned residents and interns, to the enlisted students and to all members of the faculties of medical schools. In this way, proper emphasis could be placed on military medicine, and the physicians concerned with teaching and the future medical officers would be apprised concerning recent accepted advances in the prevention, diagnosis and treatment of disease—an accomplishment that would also benefit civilian practice.

DENTAL NEEDS IN CHILDHOOD

THE report, entitled "The Dental Needs of Massachusetts Children of Today," appearing in the January 6 issue of the *Journal* cannot fail to awaken the thought of the medical profession and those concerned with public-health problems. It emphasizes the dental conditions in the Commonwealth, but dental caries is a national problem and exists in its rampant form wherever the pattern of our present civilization is found. This report is a dual challenge, both to dentists and to the medical profession.

The immediate challenge is to the dental profession to find new or more efficient technics and methods that will restore the ravages of dental caries in our youth before the age of induction into the armed forces. One might even suggest the slogan, "Treat the teeth and win the war." When one recalls the appalling number of draftees who are rejected because of dental conditions and the reported number of extractions and dental restorations that are made by dentists in the armed forces, it is not difficult to appreciate what a burden the dental problem has been on the war effort. This curtailment of efficiency is just as real as the hazards of production caused by strikes or by industrial or tropical diseases. The immediate problem is to organize some program that will ensure adequate dentistry for all boys from the ages of approximately twelve to eighteen. If this is accomplished,

it is not too fantastic to believe that the final date of the ending of the war might be changed. Although the dental profession has been stripped of its youth, it is not too much to believe that the remaining dentists, if organized, could care for this age group. It would necessitate new clinics, reorganization of technical procedures, proper compensation for services rendered, and possibly some neglect of the dental problems of those beyond the draft age. As an emergency measure, dental attention for this age group should be made compulsory, just as is vaccination against smallpox.

Prevention, the second challenge of this report, is the same as that met by groups of pioneers in other fields of medicine. It is the challenge that has practically controlled tuberculosis, syphilis and innumerable other diseases. A great industry is not satisfied to employ skilled engineers to care for its injured: it develops new machinery and new safeguards until the effects of accidents are reduced or eliminated.

Although the prevention of dental caries is not a war problem, it is one of the peace to come. As has been explained in the report of the committee, the etiology of dental caries is unknown. Students in this field believe that the best lead is through the study of nutrition. Whether it is due to some chemical disturbance in the organic structure of the tooth or to a defect in calcification is a problem yet to be solved. An example that has been utilized, namely that of a post placed in the ground with subsequent decay depending on its structure, is apt. Undoubtedly, the tooth structure is laid down in utero, and the first few weeks of life must have a profound effect on the formation of the tooth. Caries may well be due to faulty construction, and to determine when and why this occurs is a challenge to both the dental and the medical profession.

MEDICAL EPONYM

PONCET'S DISEASE

Antonin Poncet (1849-1913), professor of surgery von, published a paper, entitled "Faits de tuberculose simulant des lésions rhumatismales chroniques déformantes [Tuberculous lesions simulating the Lesions of Chronic

"deforming Rheumatism]" in *La lancette française, gazette des hôpitaux civils et militaires* (70:1219, 1897), a portion of which is translated below:

On very careful examination it is seen that we are dealing with a deforming polyarthrititis of tuberculous nature. It is a bacillary bony manifestation, usually in young subjects. It may be seen in older persons and then is difficult to distinguish from chronic deforming rheumatism.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

STATED MEETING OF THE COUNCIL

A stated meeting of the Council will be held in John Ware Hall, Boston Medical Library, 8 Fenway, on Wednesday, February 2, 1944, at 10.00 a.m.

Business:

1. Call to order at 10.00 a.m.
2. Presentation of record of meeting held October 6, 1943, as published in the *New England Journal of Medicine*, issue of November 25, 1943
3. Report of Auditing Committee and of Treasurer.
4. Reports of standing and special committees
5. Appointment of Delegates.
 - (a) To the House of Delegates, American Medical Association, for two years from June 1, 1944
 - (b) To the annual meetings of the five New England state medical societies in 1944.
 - (c) To the Annual Congress of the American Medical Association on Medical Education and Licensure at the Palmer House, Chicago, February 12 to 15, 1944.
6. Such other business as may lawfully come before this meeting.

MICHAEL A. TIGHE, M.D., *Secretary*

SECRETARY'S OFFICE

The following statement is submitted for publication in the *Journal* by order of the Executive Committee.

MICHAEL A. TIGHE, *Secretary*

* * *

The *Boston Herald*, issue of December 22, 1943, carried a news item to the effect that graduates of the Middlesex University School of Medicine, under a ruling issued from the office of the Surgeon General of the Army of the United States, would no longer be eligible for commissions in the Army Medical Corps.

In this item, C. Ruggles Smith, registrar and general counsel of this school, is quoted as suggesting that "the probable reason" for this action "was pressure from the American Medical Association."

A clipping of this item was sent to Dr. Olin West, secretary of the American Medical Association, whose reply is as follows:

December 27, 1943

Dr. Michael A. Tighe
Secretary, Massachusetts Medical Society
8 Fenway
Boston, Massachusetts

Dear Doctor Tighe:

Your letter of December 22 was delivered to this office this morning. I have read the newspaper clipping which was enclosed with your letter and have, of course, noted particularly the statement attributed to C. Ruggles Smith to the effect that the probable reason why recent graduates of Mid-
no less than
"press
turning
for De
Genera

of Middlesex would not be commissioned as medical officers until a copy of the order of the board of the Army of the United States is received. In so far as the Association is concerned, we had already been discriminated and discriminated. I sincerely hope that you have had a delightful Christmas Season and that the New Year will bring you a full measure of health and happiness. With all good wishes, I am

Very truly yours,

[Signed] Olin West

On December 23, 1943, the Massachusetts Medical Society received the first authoritative word on this subject when it received the following memorandum from the office of the Surgeon General.

WAR DEPARTMENT
Army Service Forces
Office of The Surgeon General
Washington 25

3 December 1943

MEMORANDUM FOR The Executive Officer,
Procurement & Assignment Service,
War Manpower Commission,
Room 609, 1778 Pennsylvania Avenue, N.W.,
Washington 25, D.C.

Subject: Discontinuance of Appointments in the Medical Corps Army of the United States, of Graduates of Middlesex University College of Medicine, Waltham, Massachusetts

1 It has been decided that effective this date, and including those cases now in process, that this office will no longer recommend the appointment of graduates of subject medical school as commissioned officers in the Medical Corps, Army of the United States

2 This memorandum is submitted for your information
For The Surgeon General

COMMITTEE TO AID THE DISTRICT RATIONING OFFICER

The committee of the Massachusetts Medical Society appointed last June to aid the district rationing officer has met several times with the representative in charge of food rationing of the Office of Price Administration, and has considered carefully a considerable number of physicians' certificates of patient's necessity. The majority of these requests have been granted; with many, however, it has been necessary to cut the amounts of food requested to a maximum allowance that was determined after conference with a number of recognized authorities. In others, only the basic ration has been approved.

This maximum was established as 32 pounds of processed foods and 40 pounds of meats and fats for a two-month period, or roughly double the amounts received on basic rations. These maximum amounts have been exceeded only in special cases, and only after review by the medical committee.

It has become increasingly evident, however, that an alarmingly large number of requests are being made to the rationing boards, and are being granted if they call for amounts of rationed foods within the prescribed maximum limits. Although the exact number is undetermined, it probably runs well into the thousands, and is a just cause for concern, since, with a restricted available quantity of certain foods,

to military manuals, such as those published by the War Department and those sponsored by the National Research Council. Secondly, pertinent directives and monthly bulletins issued by the Army and Navy to their medical officers on active duty should also be forwarded to the commissioned residents and interns, to the enlisted students and to all members of the faculties of medical schools. In this way, proper emphasis could be placed on military medicine, and the physicians concerned with teaching and the future medical officers would be apprised concerning recent accepted advances in the prevention, diagnosis and treatment of disease—an accomplishment that would also benefit civilian practice.

DENTAL NEEDS IN CHILDHOOD

THE report, entitled "The Dental Needs of Massachusetts Children of Today," appearing in the January 6 issue of the *Journal* cannot fail to awaken the thought of the medical profession and those concerned with public-health problems. It emphasizes the dental conditions in the Commonwealth, but dental caries is a national problem and exists in its rampant form wherever the pattern of our present civilization is found. This report is a dual challenge, both to dentists and to the medical profession.

The immediate challenge is to the dental profession to find new or more efficient technics and methods that will restore the ravages of dental caries in our youth before the age of induction into the armed forces. One might even suggest the slogan, "Treat the teeth and win the war." When one recalls the appalling number of draftees who are rejected because of dental conditions and the reported number of extractions and dental restorations that are made by dentists in the armed forces, it is not difficult to appreciate what a burden the dental problem has been on the war effort. This curtailment of efficiency is just as real as the hazards of production caused by strikes or by industrial or tropical diseases. The immediate problem is to organize some program that will ensure adequate dentistry for all boys from the ages of approximately twelve to eighteen. If this could be accomplished,

it is not too fantastic to believe that the final date of the ending of the war might be changed. Although the dental profession has been stripped of its youth, it is not too much to believe that the remaining dentists, if organized, could care for this age group. It would necessitate new clinics, reorganization of technical procedures, proper compensation for services rendered, and possibly some neglect of the dental problems of those beyond the draft age. As an emergency measure, dental attention for this age group should be made compulsory, just as is vaccination against smallpox.

Prevention, the second challenge of this report is the same as that met by groups of pioneers in other fields of medicine. It is the challenge that has practically controlled tuberculosis, syphilis and innumerable other diseases. A great industry is not satisfied to employ skilled engineers to care for the injured: it develops new machinery and new safeguards until the effects of accidents are reduced or eliminated.

Although the prevention of dental caries is not a war problem, it is one of the peace to come. As has been explained in the report of the committee, the etiology of dental caries is unknown. Students in this field believe that the best lead is through the study of nutrition. Whether it is due to some chemical disturbance in the organic structure of the tooth or to a defect in calcification is a problem yet to be solved. An example that has been utilized, namely that of a post placed in the ground with subsequent decay depending on its structure, is apt. Undoubtedly, the tooth structure is laid down in utero and the first few weeks of life must have a profound effect on the formation of the tooth. Caries may well be due to faulty construction, and to determine when and why this occurs is a challenge to both the dental and the medical profession.

REFRIGERATION IN SURGERY OF THE EXTREMITIES

PAUL R. HINCHY, M.D.*

SALEM, MASSACHUSETTS

THIS paper was originally completed as a case report of an unusually severe spreading infection of an arm, in which an unexpectedly favorable outcome followed the employment of a tourniquet and ice refrigeration prior to amputation. Refrigeration proved so gratifying, however, that the members of the Surgical Service at the Salem Hospital were encouraged to employ this form of therapy in several other suitable cases in which trial of this method seemed reasonable.

Broadly speaking, refrigeration therapy has been advocated for three types of surgical lesions of the extremities: arteriosclerosis with circulatory insufficiency, uncontrollable limb sepsis and severe trauma to the limbs with circulatory impairment. Our case total is small, but our experiences have been illuminating. Case reports illustrative of each of these three types of surgical lesions of the extremities are submitted in the order in which they were encountered.

LIMB SEPSIS

The first case was that of a desperately ill and toxic patient who had uncontrollable sepsis in a cold, pulseless arm, with beginning gangrene of the hand.

CASE 1. A 54-year-old leather worker was admitted to the Salem Hospital on December 17, 1942. Because of his toxic condition and language difficulty, no adequate history was obtained at entry, nor was it possible to obtain additional information later on. Apparently, a small break in the skin of the forearm had occurred at work 10 days prior to admission. There was also a questionable history of chrome dermatitis, with some pruritus and scratching. Five days prior to entry the forearm became swollen and the patient resorted to alcohol for relief. He continued at work until the day before entry. He had sought no medical advice prior to admission. On the night of entry the left hand had begun to turn black.

The patient was a strong, middle-aged laborer, rational but unco-operative. The temperature on admission was 102.6°F., the pulse 110, and the respirations 46. The white-cell count was 6100 and the hemoglobin 97 per cent. The blood pressure in the Out Patient Department at entry was 80/54. The left arm and hand were tremendously swollen and cool, and cyanotic to 7 cm. below the level of the shoulder joint. The coldness and cyanosis were progressively more marked as the hand was approached. The superficial layers of the skin over the lower forearm, wrist and hand had separated from the deeper layers, and there were multiple, thin-walled vesicles and bullae filled with blood-tinged watery fluid. The radial pulse was not felt, but a brachial pulse was

present. The hand was blue to black. The entire arm was extremely painful to touch. The appearance of the arm and the fact that it was a winter night suggested to the house officer an admission diagnosis of frostbite. Routine shock treatment was instituted, and 2 hours after entry a feeble radial pulse could be felt in the affected arm. On the night of entry, treatment consisted of continuous hot packs to the entire left arm and intravenous sodium sulfadiazine.

During the night of admission the systolic blood pressure ranged from 70 to 90. On the following morning the tem-

FIGURE 1. Photograph of the Left Lower Forearm and Wrist Fifteen Hours After Admission.

perature was 103.8°F., the pulse 120, and the respirations 35. Twelve hours after entry, the patient was seen by four senior surgeons. He was extremely noisy and unco-operative and appeared very toxic. The face showed an ashen-gray hue, although the blood pressure was then 118/84. The entire left arm was cyanotic; most of the bullae had ruptured during

*Assistant in surgery, Harvard Medical School and Tufts College Medical School; junior surgeon, Salem Hospital.

the night (Fig. 1); no radial pulse could be felt despite the adequate blood pressure. The sulfadiazine level was 17.6 mg. per 100 cc. There had been no report on the blood culture or on the cultures of the fluid from the bullae. There was an even division of opinion among the consultants concerning the wisdom of immediate amputation, in contrast to a policy of delay with the hope of improvement in the general condition. Opinion was unanimous, however, that whatever course was followed, the patient was almost surely going to die. In this dilemma, application of a tourniquet and refrigeration seemed worthy of trial.

Accordingly, the entire left arm was packed in ice and a tight tourniquet was applied to the upper arm 7 cm. below the shoulder, using three turns of gum-rubber tubing. At that time it was planned to amputate the arm in a few hours,

FIGURE 2. Photograph of the Stump Prior to the Minor Operations.

but the patient, who was then partly delirious, refused permission. That afternoon the white-cell count was 5400.

On December 19, after 20 hours of tourniquet and refrigeration, there was an obvious dramatic change in the patient's condition and appearance. The temperature had dropped to 100.4°F., the pulse to 110, and the respirations to 20. He was quiet and oriented, had begun to take fluids by mouth, and appeared much less toxic. The skin was dry and warm, and the radial pulse in the opposite wrist improved in quality. By that time the blood culture had shown the presence of a hemolytic *Staphylococcus aureus*. Culture from the bleb fluid had shown the same organism and an anaerobic nonhemolytic streptococcus. Shaved ice had been used for refrigeration, but because an improvised apparatus was used, refrigeration up to the level of the tourniquet was incomplete. Nevertheless there was absolutely no sensation below the level of the tourniquet. Amputation was therefore performed 24 hours after the commencement of refrigeration and 36 hours after entry. Preoperative medication consisted of $\frac{1}{4}$ gr. of morphine sulfate and 1/150 gr. of scopolamine hydrobromide 1 hour before operation. An additional $\frac{1}{4}$ gr. of morphine sulfate was administered in the operating room, since the patient was wide awake. Nevertheless, he remained awake throughout the operation.

The operation was performed by Dr. D. S. Clark. The left forearm was prepared and draped. The tourniquet was not removed. A guillotine amputation was then done, with no other anesthesia than refrigeration and the tourniquet. No pus was encountered. The soft tissues were surprisingly firm, glistening and fairly normal in color. The transected muscle bundles had the appearance of well-refrigerated meat. Although the patient was wide awake and talking throughout

the operation he did not complain or show signs of discomfort at any time. No sutures were employed.

Thereafter the amputated arm was completely dissected by me. The tissues were edematous, but there was no evidence of any accumulation of pus. All the main arteries and veins were examined but no evidence of thrombosis was present.

The 7-cm. stump of the left arm was not refrigerated post-operatively, which was perhaps a mistake. The patient had a stormy convalescence for 10 days and was persistently disoriented, incontinent and cyanotic. The red-cell count dropped to 2,000,000. Extensive sloughing occurred in the narrow band of tissue below the level of the tourniquet, which had had to be left on for many hours. Surgeons with considerable experience with refrigeration have stated that amputation may be done at almost any level below the tourniquet in those limbs in which amputation is performed within four or five hours of the application of the tourniquet and the commencement of refrigeration. The patient was ambulant 1 week after the operation. Two subsequent minor operations were required to remove protruding bone and to approximate loosely the margins of the wound (Fig. 2).

The patient was discharged on March 1, 2½ months after entry, with the stump of the left upper arm well healed. He was last seen on May 1; he had gained 26 pounds in weight, felt well, and had no symptoms in the stump.

It seems worth while to present this report because the case was such a dramatic demonstration of the value of the application of a tourniquet and refrigeration. It is the conviction of all the senior surgeons that the patient would have died if he had been treated either by immediate surgery or by hopeful delay. The overwhelming toxicity due to sepsis, together with the clear evidence of marked circulatory deficiency in the limb, presumably due to vasospasm and edema, did not augur success for formerly accepted routines of treatment. Toxicity secondary to infection had produced a more or less intractable shock that could not be fully combated. The trauma of anesthesia and operation, added to the already existing shock, would almost certainly have been disastrous. Because of the impaired circulation to the limb, chemotherapy and the natural defenses of the circulation were destined to failure because the effective agent could not be brought to the site of the sepsis in therapeutic concentration. The initial treatment by hot pack was probably harmful, since the patient was in shock and the limb was not capable of a reactive hyperemia because of the vasospasm that was presumably present. Moreover, any increase in blood supply to the affected limb brought about by vasodilatation due to heat must have been more than offset by the accelerated metabolic demand for oxygen on the part of the anoxic tissues. But although an adequate blood supply and effective chemotherapy could not be provided at the local site of infection, it was obvious that toxins and bacteria were being liberated freely into the systemic circulation from the limb.

We asked ourselves whether the limb could be saved by refrigeration and systemic chemotherapy without the use of a tourniquet. Two considerations prevailed against this. In the first place, the cold, cyanotic, pulseless forearm and hand strongly suggested the onset of gangrene, so much so that it was unanimously thought that arterial thrombosis had

occurred because of intimal damage from pressure and sepsis together with peripheral circulatory failure. Moreover, it was apparent that the immediate physiologic amputation of the septic limb by a tightly applied tourniquet was imperative in order to put a quick stop to the continued entrance of bacteria and toxin into the general circulation. Refrigeration alone could not have produced any such an immediate result.

LIMB TRAUMA

Several recent cases of severe limb trauma treated at the Salem Hospital have suggested a number of questions concerning the value of refrigeration in such conditions. The following case is cited as an example.

CASE 2. A 9-year-old boy sustained a severe, crushing compound fracture of the right index, middle and ring fingers when a mahoe cover fell on them. When he was first seen in the operating room 1½ hours after the accident, a complete compound fracture with fairly extensive laceration of the adjacent soft parts was found in all three fingers, just inside the proximal interphalangeal joints. Distal to this level of fracture the fingers were slightly cyanotic. It was recognized that there was serious circulatory impairment, but it was decided to be conservative. Accordingly the wounds were thoroughly irrigated by saline solution. The wound was dusted with sulfanilamide powder and skeletal traction fixation was secured by pins through the distal phalanx. Continuous refrigeration by shaved ice was employed with only a thin layer of gauze over the wound and with the fingers fixed in elastic-band traction on an arm board.

The arm was then elevated, and more or less continuous refrigeration was maintained for 12 days. No sign of sepsis appeared. During the 1st week the patient repeatedly stated that he was free of pain when his hand had been freshly iced, but that he had considerable discomfort after the ice had melted and until it was renewed. It was not known how long refrigeration should be maintained, but after 1 week the loosely covered hand was exposed to the air without refrigeration for varying periods. During this first week it was hoped that refrigeration was maintaining an equilibrium between the known impaired circulation and the local metabolic demand of the fingertips, reduced by the refrigeration. On several occasions, there appeared to be a suggestive, pinkish suffusion of the distal fingers. Certainly the flesh continued to look healthy and no cyanosis appeared. As the interval without refrigeration was increased, however, it quickly became apparent that we had succeeded only in refrigerating dead tissue so that frank decomposition was forestalled. A few hours after refrigeration was withdrawn altogether, obvious gangrene was readily apparent. Amputation of the three fingers was finally necessitated at the same level at which it would have been done at entry. Convalescence was uneventful.*

The chief question that this experience brought to our minds was, For what length of time may one employ refrigeration with continued hope of improvement in such a borderline trauma with circulatory impairment?

Several recent papers assert the value of refrigeration in the management of limb trauma both in civil and in military practice. For the occasional case in which it is indicated, the procedure is simple and deserving of consideration. Even small hospitals can afford the equipment.

ARTERIOSCLEROSIS WITH GANGRENE

Recently, a splendid opportunity was afforded to make a comparison between refrigeration anesthesia

and one of the previously accepted forms of anesthesia, as employed in amputation of limbs for arteriosclerotic gangrene. Within one month an elderly patient was obliged to undergo amputation of both legs through the thigh because of arteriosclerotic gangrene associated with diabetes. For the first amputation, cyclopropane and nitrous oxide anesthesia was satisfactorily employed. More recently the second limb was removed under ice anesthesia together with the usual sedation.

CASE 3. A 70-year-old man with mild diabetes mellitus had narrowly escaped amputation of the left leg in the fall of 1942, when he was required to spend 3 months on the surgical ward and to undergo three minor local operations because of a septic blister on a toe. Optimism for such conservative surgical management seemed warranted by the presence of good pulsation of the dorsalis pedis artery and by the ready controlling of the mild diabetes. The patient, however, maintained no satisfactory regime of peripheral vascular hygiene, and in August, 1943, returned with frank gangrene of one of the toes of the right foot. There was no pulsation in this foot. Accordingly, on September 14 a routine midhigh amputation of the right leg was performed under cyclopropane and nitrous oxide anesthesia, which was quite satisfactory. Ordinarily spinal anesthesia would have been employed. Refrigeration anesthesia had been mentioned as a possibility. The operation required 35 minutes. The stump was dusted with sulfanilamide powder and closed without drainage. One hour later the patient complained of considerable pain in the leg. Three hours later, a preoperative blood pressure of 132/66 had dropped to 102/60. The patient was nauseated and showed signs of mild shock, for which elevation of the foot of the bed, warm blankets and Neo-Synephrine were employed.

The temperature first returned to normal on the 5th postoperative day. The patient did not get out of bed until the 7th day. He experienced the usual amount of postoperative pain. The stump dressing forewent several times in uneventful except for severe skin edges. The level of blood sugar was controlled with a little difficulty.

During the next 3 weeks, the tips of two toes on the left foot steadily became discolored. In addition, superficial sepsis at the site of a thickened callus at the base of the little toe progressed to involve the deeper tissues and eventuated into a chronic ulcer with an associated x-ray finding of complete destruction of the head of the 5th metatarsal bone. It was assumed that a Mönckeberg type of sclerosis of the small vessels existed, coincident with the diabetes, since satisfactory pulsation of the dorsalis pedis artery could be felt. During this period of waiting it was difficult to prevent those on the ward having care of the patient from employing heat from 100-watt bulbs directly over the weeping ulcer with the aim of drying up the lesion.

Finally, on October 18, the second limb was amputated through the thigh. Preliminary sedation was secured with Pantopon, scopolamine and 2 ounces of whisky. A 6-hour period of cracked-ice refrigeration was employed. A supracondylar amputation was done, since it was thought that less shock would attend tissue trauma through the tendons at this level than through the muscle masses at mid thigh.* Thirty-five minutes was consumed in performing the operation. The patient grimaced when the sciatic nerve was crushed and cut across. It was thereafter injected with 3 cc. of absolute alcohol. Otherwise, he felt no pain. No chemotherapy was employed. A single layer of sutures approximated the muscle group.

The patient sat up in bed and ate lunch 1 hour after the completion of operation. He sat up in a chair that afternoon and every day thereafter. He did not go into shock, as was the case after the first operation. The postoperative pain was about the same as after the first operation. The temperature became normal on the 4th postoperative day. The

*Amputations below the knee in occlusive arterial disease have recently been proposed by Ricket and Ghormley,¹¹ in cases in which adequate circulation at this level justifies the procedure. They argue that the chance for a later satisfactory prosthesis is appreciably greater than if the usual midhigh amputation is done.

dressings showed no staining, in contrast to the first amputation. Nausea and vomiting, however, were a little more pronounced after this operation than after the first, possibly because of the release of the tourniquet just prior to amputation. (It has been argued that premature release of a tourniquet may be productive of shock, due to absorption of histotoxins, in patients in whom widespread sepsis or severe tissue trauma exists.) The diabetes showed about the same reaction to this second amputation as to the first. Wound healing progressed uneventfully.

This case demonstrated that it is possible to secure satisfactory anesthesia by ice refrigeration. The mechanics of such anesthesia proved to be more of a chore than is the case with the usual low-spinal anesthesia. It is the impression of several surgical observers that the postoperative convalescence after the second amputation using refrigeration anesthesia was definitely more satisfactory than that after the first operation but the percentage of improvement was perhaps a small return for the additional work required. Hence, we are not yet willing to resort to this cumbersome procedure for anesthesia as a routine for all amputations in arteriosclerotic gangrene. We have been convinced that satisfactory anesthesia can be secured by the method, and that there are occasional cases in which its employment provides the most satisfactory solution to the problems of securing anesthesia and minimizing systemic reaction to surgery of the extremities.

DISCUSSION

Clinical use of the principle of refrigeration of limbs is concerned almost exclusively with those limbs in which efficient circulation does not exist. Following the pioneer lead of Fay,² Allen³⁻⁷ elaborated on the principle of refrigeration. Thereafter Smith,⁸ McCravey,⁹ and Whittemore, Lisa and Sauer,¹⁰ made further contributions. From Allen's experimental observations on tissue asphyxia in relation to the temperature of the environment, he was prompted to study the survival time of tissues with inadequate blood supply when exposed to heat and to cold. Heat accelerated necrosis, whereas cold markedly prolonged the survival time of anemic tissues. Oxygen consumption of the tissues is reduced progressively for each degree Centigrade by which tissue temperature is lowered. Allen made the first clinical application of laboratory observation in cases of arteriosclerotic gangrene of the leg. Subsequently, the value of refrigeration in arteriosclerotic gangrene and in limb sepsis and trauma has been repeatedly confirmed by Allen and all other observers¹¹⁻¹⁷ who have made the clinical trial. It is worthy of repeated emphasis that the essential feature in all these cases has been a deficient circulation to the limb. Very few observers have claimed any merit for refrigeration when normal circulation is present. Conditions of trauma or of sepsis can be better handled by the tissues with the aid of their normal physiologic inflammatory reaction than by suppression of this reaction by refrigeration. The assets of this normal inflammatory response are

increased exudate, increased absorption and increased local heating of tissues with accelerated tissue metabolism. At the same time there is a greatly increased tissue demand for oxygen, out of proportion to the increased local blood flow. In a limb with deficient circulation, a disparity may exist between the supply and the demand for oxygen on the part of the tissue cells; hence, necrosis of tissue may occur if an inflammatory response is provoked. The refrigeration of such tissues is beneficial because it retards the oxygen demand of the tissues to a level commensurate with the available oxygen brought to the limb by the deficient circulation. This metabolic adaptation is apparently the principal benefit resulting from refrigeration, but there are a number of other advantages emphasized by Allen and confirmed by almost all investigators, as follows. First, there is efficient anesthesia, secured by the action of refrigeration on nerve trunks and also by what Allen terms "anesthesia of protoplasm." Second, anesthesia of protoplasm, in contrast to nerve anesthesia, is said to be a factor in preventing shock; shock is also lessened by the diminished tissue necrosis, diminished bacterial growth and the diminished absorption from the local site because of the vasoconstriction brought about by refrigeration. Third, local infection and edema are inhibited. This is in line with the familiar preservation of tissues in an icebox for days or weeks. Fourth, desired drainage from an amputation stump for the first few postoperative days is facilitated, because cooling of the tissues prevents the usual agglutination of the wound edges. Thus, postoperative sepsis in the stump is minimized. Lastly, the tendency to thrombosis and intimal damage of blood vessels is greatly lessened. Venous thrombosis in amputated stump has recently been emphasized by Veal¹⁸ as a frequent cause of postoperative fatality, owing to subsequent embolism.

It has been demonstrated by experimental and clinical experience that all the above benefits may be conferred on patients, in varying degrees, by the process of refrigeration alone, except that anesthesia is not so complete. In clinical practice, however, refrigeration and a tightly applied tourniquet are usually employed, except in occasional cases where a reasonable hope of survival of the affected limb exists. Even in this situation a tourniquet may be applied to the refrigerated limb for some hours and perhaps several days, without compelling amputation because of necrosis distal to the tourniquet. It is necessary, therefore, to give some consideration to the role that the tourniquet plays in the improvement of the patient's condition. First, toxic absorption from a hopelessly traumatized limb or a septic limb is controlled. The tourniquet also plays a significant role in the control of shock resulting from a septic or traumatized limb, as shown in recent studies by Duncan and Blalock.¹⁹ Lastly, the boon of adequate anesthesia by refrigeration is often lost

unless a tightly applied tourniquet has completely shut off available circulation, since successful chilling of tissues is directly proportioned to the degree of reduced blood flow. In our reported case of sepsis there can be no question that the immediate physiologic amputation of the septic limb by a tight tourniquet was highly useful in the control of toxic and septic absorption.

Technic

The essential points of technic with tourniquet and refrigeration have been fairly well established. The refrigeration of limbs has been secured by shaved ice, ice water, or electric or gas refrigeration units.

FIGURE 3. Photograph of the Refrigeration Box.

A common device is to employ a rectangular box into which the affected limb can be placed, and then surrounded by ice. We secured a refrigeration box modeled after the one proposed by Gordon²⁰ (Fig. 3). Preliminary refrigeration by ice bags at the level of application of the tourniquet will suffice after a few minutes to permit a tight application of narrow gum-rubber tubing applied several times around the limb. Allen²¹ states that a narrow tourniquet is more satisfactory than a broad one. Incomplete anesthesia may result if the tourniquet is not tightly applied, since it will be more difficult to refrigerate the tissue. The limb must be refrigerated to the level of the tourniquet. The desired level of temperature is about 5°C. which will effectively chill the tissues without actually freezing them. Lake²² has found that at a temperature of -6°C. all metabolic processes are inhibited. Therefore the thermal level of refrig-

eration is important, since actual freezing causes irreparable tissue damage, with the loss of large amounts of protein fluid at the site.²³ If saving the refrigerated limb is contemplated, actual freezing must be guarded against by skin-temperature readings. The temperature of the limb immersed in ice may be recorded by thermostat or by simple thermometers held against it. In a patient in good general condition, amputation through the lower thigh may be done with complete refrigeration anesthesia after two and a half hours. Amputation just below the knee requires about two hours for satisfactory anesthesia. A progressively shorter time is required as one approaches the foot because of the diminished mass of the limb and the increased ease of thorough chilling. If the amputation is done within six hours of the application of the tourniquet, almost any level of amputation distal to the tourniquet may be selected with confidence that healing will occur. If the tourniquet is to be left on longer than six hours, it should not be removed prior to operation, since overwhelming shock or generalized sepsis may result from its premature release.⁹ When a tourniquet has been left on for longer than six hours, amputation must be done at or within a few inches of the level of the tourniquet. Refrigeration greatly prolongs the safe period during which a tight tourniquet may be applied. Hence it is suggested that refrigeration is adaptable to wartime injuries of the extremities because it lengthens the safe period of tourniquet application and provides complete anesthesia for later surgery.²⁴ In poor risk patients, the tourniquet may be left on for as long as two days while the general condition is being improved. Preliminary sedation may be administered prior to the operation, but oftentimes it is unnecessary. Whiskey is a good sedative for elderly arteriosclerotic patients.

It is a common experience to obtain complete anesthesia by refrigeration and tourniquet only, without the use of any other agents. The two procedures that test the adequacy of refrigeration anesthesia are the cutting of the sciatic nerve at mid thigh and the sawing of the femur. Following operation, it has been recommended by Allen¹⁰ that refrigeration of the stump be maintained by means of ice bags against a thin dressing, gradually reducing the refrigeration over a period of several days. A number of writers^{13, 14} have commented on the fact that elderly, poor-risk patients are able to return to their rooms, sit up out of bed on the day of operation, and eat their meals, in contrast to the usual weakness and depression of similar patients who have received spinal anesthesia for leg amputation. Wound healing is steady, although slower, with refrigeration. Stump sepsis is said to be lessened, presumably on the basis that postoperative wound drainage is usually more profuse, since the refrigeration inhibits the normal agglutination of the wound margins. Haley¹² comments that a rise in

postoperative temperature after an amputation done under refrigeration anesthesia is not so prolonged as after amputation under spinal anesthesia.

Indications for Use

Arteriosclerotic gangrene. This has been the most frequent lesion in which refrigeration anesthesia has been used. Two distinct types of cases have been treated. When amputation is inevitable in nontoxic patients in poor general condition, the application of a tourniquet and refrigeration have provided a quick, satisfactory anesthesia within several hours, accompanied by minimal reaction to the operative procedure. On the other hand, if spreading sepsis predominates in the arteriosclerotic limb, permanent and continuous refrigeration may be employed for a period of days while the general condition is being improved.

Sepsis. Cases similar to the one reported in which a previously normal limb is the site of uncontrollable sepsis have been infrequently reported. Refrigeration appears to be efficacious in forestalling the spread of sepsis.

Military wounds. Allen and Crossman²¹ have stated that tourniquet refrigeration provides freedom from pain, hemorrhage, shock and infection and allows either an immediate operation without other anesthesia or long deferment of operation without harm, if such a step is indicated. They emphasize that the safe period for the application of the tourniquet is greatly lengthened by refrigeration. They point out that refrigeration is usually available on naval vessels, and that a 200-pound apparatus that can be operated by the motor of a truck will refrigerate four to six limbs simultaneously. Bowers²⁵ has related favorable experiences in the treatment of cases of vascular trauma of the extremities encountered in a station hospital (Camp Gruber, Oklahoma). He found the fluorescein circulation-time test to be of value in the estimation of circulatory adequacy in refrigerated limbs. Criteria of failure of compensatory collateral circulation are listed.

Miscellaneous. Holman²⁶ suggests that in cases of limb trauma accompanied by concussion of the main artery with subsequent segmental arterial spasm, initial refrigeration enhances the survival of such a limb. In the immersion-foot syndrome, the principle of refrigeration has been employed to provide therapeutic cooling of hyperemic painful feet during the early stages.^{27, 28} Such cooling without actual refrigeration is also useful in cases of frostbite, and we have recently treated a patient with moderately severe frostbite in this manner. Mock²⁹ has successfully employed refrigeration anesthesia for the taking of skin grafts from the thigh.

SUMMARY

The principle of refrigeration has been established as a useful and at times lifesaving procedure in the

management of arteriosclerotic limbs with gangrene. A case is cited in which refrigeration anesthesia is favorably compared with general anesthesia.

Refrigeration may also be employed successfully in certain cases of trauma or sepsis of the limbs. A case is reported in which it is suggested that life was saved by the employment of refrigeration and a tourniquet.

AN ERUPTIVE FEVER INVOLVING THE MOUTH AND EYES (STEVENS-JOHNSON'S DISEASE)*

Report of a Case

ROBERT C. MURPHY, JR., M.D.†

NEW YORK CITY

IN 1922, "a new eruptive fever associated with stomatitis and ophthalmia" was reported by Stevens and Johnson.¹ A score of similar cases have since been added to the literature, all with unwieldy names, such as "erythema multiforme bullosum with involvement of the mucous membranes of the eyes and mouth."² No suitable name has been proposed for this disease, which appears, as cases accumulate, to merit recognition as a discrete syndrome. It is a bizarre disease of dramatic onset and course, and there are so many features common to each reported case that it seems justifiable to separate them from erythema multiforme and other established entities of this order.

This disease is one of acute, sometimes fulminating, systemic reaction with fever and prostration, erythematous generalized skin rash and severe stomatitis, followed by sloughing. With occasional exceptions³ the conjunctivas are involved. The usual period until resolution of the skin lesions is about three weeks.² All laboratory studies have revealed normal or variable findings, including blood-cell counts, blood cultures,⁴ smears and cultures of lesions,^{4, 5} a skin biopsy⁶ and studies of the chemical constituents of the blood.⁴ The suggestion that Vincent's stomatitis may be associated etiologically with the disease⁶ has not been confirmed.²

The following case is reported because it illustrates clearly the most constant clinical findings of this disease.

CASE REPORT

J. M., a 22-year-old, unmarried man of Italian parentage, was admitted to St. Luke's Hospital on February 5, 1943, complaining of blisters in his mouth that had first appeared 2 days before admission, and had progressed since that time. He had had no previous illnesses, and had enjoyed excellent health except for a moderate tendency to upper respiratory infections. He had had a cough and mild malaise in the 2 weeks previous to admission. He had recently used an elixir of terpene hydrate and codeine, and had taken a few tablets compounded of aspirin, acetphenetidin and caffeine, but no other drugs. He had also gargled with a strong solution of

sodium chloride. The present illness began 3 days before admission with a swelling between the upper lip and gum, where the patient noticed burning on taking food. Later blisters began to appear on the buccal mucous membrane.

Physical examination showed a well-developed and well-nourished, swarthy-skinned man who appeared comfortable. The temperature was 101°F., the pulse 120, and the blood pressure 112/76. The conjunctivas were diffusely inflamed. The buccal mucous membrane, gums, palate and uvula were covered with many tight vesicles the size, shape and color of medium-sized pearls. There was also a small amount of red inflammatory reaction and sticky exudate about the urethral meatus. The rest of the examination was negative.

Routine laboratory studies showed a normal chest film and electrocardiogram. The urea nitrogen was normal, and a blood serologic test for syphilis was negative. The red-cell sedimentation rate was slightly elevated (33 mm. per hour), which may have been caused by the respiratory infection.

The patient remained in the hospital for 17 days. During the first 2

course. The ran a hectic gressed with striking speed during this time. All the pearl-like vesicles in the mouth quickly ruptured, leaving a loose, dirty, whitish slough. By the 3rd day there was a massive slough several millimeters deep affecting the entire mucous membrane of the mouth and sparing only the tongue, which was heavily coated. This process extended out over the lips almost to the vermillion border. The surface thus uncovered was raw and angry red, and bled easily when touched. The nasal mucous membrane sloughed in the same, though a less dramatic, manner. Large blebs appeared on the glans penis and one on the corona, both also with superficial sloughs. Both conjunctivas were markedly inflamed, but no vesicles formed about the eyes. A sticky, semipurulent exudate flowed continually from the eyes. On the arms and legs a few punctate red areas began to appear and expanded, and in the center of each a tight little vesicle appeared. These vesicles ripened into thin-walled bullas, and eventually ruptured. They were scattered over all four extremities, but spared the trunk and face.

On the 5th day the temperature fell and the patient began to improve. He continued to recover gradually, although the sloughs in the mouth and on the penis were not complete before the 3rd week. Photographs taken on the day before discharge (the 16th day) show the residuums on the lips (Fig. 1), buccal mucous membrane (Fig. 2), legs (Fig. 3) and penis (Fig. 4).

The blood smears showed normal red elements and a white-cell count morphonucle.

latter figure and the white-cell count as a whole gradually fell to normal. Blood cultures and aspiration cultures of the bullas were sterile. A conjunctival culture yielded *Staphylococcus aureus*. Smears of the bullas were negative both for *Staphylococcus aureus* and for *Streptococcus* and for common heavy metals. 24-hour urine specimens.

*From the medical service of Dr. F. Warner Bishop, St. Luke's Hospital, New York City.

†Formerly, Intern, St. Luke's Hospital.

The patient had had a mercury-amalgam tooth filling 1½ months previously, but no other significant metal or drug

FIGURE 1. *Late Lesions on the Lips.*

history could be elicited from either the patient or his dentist.

The therapeutic measures employed included sulfadiazine in full doses for 5 days, the forcing of fluids, colonic irrigations, calcium gluconate intravenously and numerous salves,

FIGURE 2. *Re-epithelialization of the Lesions of the Buccal Mucous Membrane.*

washes and other local applications to the mouth, penis and eyes.

At the end of 17 days the skin lesions had crusted and mostly fallen away with healing beneath, and before the end of the 4th week the scars were barely visible.

DISCUSSION

Stevens and Johnson¹ outlined most of the features of this disease with their "two cases of an extraordinary, generalized, eruption with continued fever, inflamed buccal mucosa and severe pur-

ulent conjunctivitis." Although the skin lesions of these cases were not vesicular or bullous as in the present case and numerous others,^{2-4, 6} the appearance of the buccal mucosa was almost identical, with the formation of tight vesicles that ruptured and progressed rapidly to a membranous slough. The exact appearance of the skin lesions, in fact, appears to vary somewhat in different cases, and Stevens and Johnson even repudiated as inadequate the diagnosis

FIGURE 3. *Late Lesions on the Right Leg.*

of erythema multiforme. The reaction of the buccal mucous membrane is more characteristic. Ginandes's⁴ description of the mouth lesions corresponds exactly with the picture presented on about the fourth hospital day, in the case above: "The entire buccal mucosa was red, ulcerated in spots and covered with a whitish pseudomembrane which was friable and appeared like ruptured bullas. These lesions varied in size and were surrounded by a zone of marked congestion. The hard and soft palates were diffusely mottled and similarly covered with greyish-white patches." In almost every case in the literature,^{2, 3, 4-6} the conjunctivas were inflamed and produced a sticky, purulent exudate, as in the case

herein described. The most serious sequela reported was panophthalmitis and total destruction of the eyes, in one of Stevens and Johnson's patients. This complication is said to have occurred in several other cases.² There is only one previous report of

FIGURE 4. Late Lesions on the Glans Penis and Corona.

penile lesions,⁶ although Ageloff² described massive vaginal involvement in a four-year-old girl.

The disease is definitely in the pediatric sphere, rare exceptions being the case reported and that of Levy.³ The age limits are said to be twenty-two months and sixteen years.² With rare exceptions,² the condition is found only in male children.

SUMMARY AND CONCLUSIONS

A case is presented that is typical of a growing number of cases being reported in the literature, known by such names as "erythema multiforme bullosum with involvement of the mucous membranes." This is one of a number of obviously unsatisfactory names, since it is unwieldy, the disease is not typical of erythema multiforme, and it is the enanthem rather than the exanthem that seems to be its constant feature. The condition begins with a violent constitutional reaction with fever of abrupt onset and with marked prostration. A vesicular stomatitis develops, the vesicles rapidly burst, and a membranous slough forms that leaves a raw buccal and palatal surface behind it. There is almost invariably a diffuse conjunctivitis with a sticky, purulent exudate. This last feature may predispose to the most serious complication of the disease — panophthalmitis and permanent destruction of the eyeballs and therefore constitutes, at the present stage of knowledge, the major point of therapeutic or prophylactic departure.

Nothing is known of the fundamental nature of the disease or of its etiology. Neither drugs nor Vincent's organisms have been implicated, and no other factor of importance has even been suggested. The greatest progress to date is the recognition of the syndrome in its own right, by virtue of several isolated reports describing a closely similar picture.

PULMONARY ACTINOMYCOSIS

Treatment with Sulfonamides

NAHUM R. PILLSBURY, M.D.,* AND JOSEPH D. WASSERSUG, M.D.†

SOUTH BRAINTREE, MASSACHUSETTS

PULMONARY actinomycosis is uncommon. At the Johns Hopkins Hospital only one case was found in 12,000 consecutive autopsies.¹ The prognosis is poor and most cases end fatally.¹⁻⁵

The treatment of actinomycosis has in general been unsatisfactory. Iodine is the time-honored weapon against this fungus infection, but thymol, roentgen rays, a variety of vaccines and recently sulfonamides have been used. Masson⁶ reported clinical cures in 2 cases of abdominal actinomycosis by roentgen-ray therapy, but, as a rule, roentgen-ray treatments are only partially effective or totally ineffective. Neuber⁷ advocated "specific" vaccines, convalescent serums and autohemotherapy, but his practically 100 per cent cures still lack confirmation.

Several recent reports have stressed the effectiveness of the sulfonamides even when other treatments were at best of only slight benefit. In a case of abdominal actinomycosis, Walker⁸ reported healing three weeks after sulfanilamide was begun and after iodides had apparently proved of no value. Miller and Fell⁹ tried thymol, potassium iodide and roentgen rays, but their patient became progressively worse. Sulfanilamide therapy was instituted and improvement was noted in one week.

Sulfanilamide has also been used in pulmonary actinomycosis. Morton⁴ reviewed a case that failed to improve with 400 gr. of potassium iodide daily and roentgen-ray treatments. He stated that sulfanilamide and promin made a definite improvement in the general condition, whereas potassium iodide, even in massive doses, was of only moderate value. Of several different treatments used by Dobson, Holman and Cutting,¹⁰ sulfanilamide seemed to be the most effective therapeutic agent. Wilkinson¹¹ also obtained good results with sulfanilamide and recommended that it be given for several weeks, if necessary. Temporary benefit was obtained by Schneider and Finucane,⁵ but their patient died of complications resulting from pneumothorax and not from actinomycosis.

Sulfapyridine has been employed effectively in both abdominal and pulmonary actinomycosis. Ogilvie¹² treated a young girl with abdominal actinomycosis by massive doses of potassium iodide, but she failed to improve. Sulfapyridine was then given and the response was so favorable that the drug was discontinued in thirteen days. Mitchell¹³ tried tincture of iodine and oral actinomycotic vac-

cine, with no success. Sulfapyridine brought about prompt healing of sinuses and apparent clinical cure.

The following case of pulmonary actinomycosis is reported not only because of the rarity and seriousness of this disease, but more especially because sulfonamides appeared to be of considerable therapeutic value.

CASE REPORT

T. M. C. a 29-year-old housewife, was first admitted on September 4, 1940, after a chest roentgenogram, taken because of a tuberculous husband, had revealed tuberculosis. The past history disclosed incision of the cervical lymph nodes in 1930 and pleurisy 4 months before admission.

Physical examination was essentially negative except for a scar on the right side of the neck and fine rales in the left axilla. A roentgenogram showed areas of increased density in both lungs at the level of the first anterior intercostal space. The urine was negative. Blood examination revealed slight anemia. The sedimentation rate was increased. A Mantoux test was positive. The sputum was negative for tubercle bacilli, but a gastric specimen was positive by guinea-pig inoculation. On November 11, the patient left the hospital against advice.

On April 1, 1942, the patient was readmitted because of pain and swelling in the left chest wall, fever and marked loss of weight. One and a half months before re-entry she had gone to another hospital because of a pain in the left chest of 1 month's duration. While there, the left pleural cavity was incised and 2 cc. of thick pus was obtained. On re-entry, the patient appeared extremely ill, thin and pale. A 2-cm. scar was present just below the inferior angle of the left scapula, and a fluctuant hot swelling extended from this point downward to the tenth rib. A roentgenogram of the chest showed a density consistent with fluid in the left intrapleural space and fibrosis in the left first intercostal space. The temperature was 101° F., the pulse 140, and the respirations 28. The urine was negative. The red-cell count was 3,900,000 the hemoglobin 76 per cent, and the white-cell count 10,500. A blood Hinton test was negative. The sputum and gastric contents were negative for tubercle bacilli by concentration and guinea-pig inoculation.

The day following admission, 2cc. of thick pus was obtained by aspiration of the chest abscess. This pus proved negative for tubercle bacilli by smear, culture and guinea-pig inoculation, but a smear and culture showed *Actinomyces hominis*. Aspiration was repeated on April 10, and 150 cc. of pus containing numerous sulfur granules was obtained. Within the next 2 weeks four sinuses developed at the site of the abscess. In May the patient developed a productive cough, and sulfur granules were found in the sputum. Potassium iodide was begun on May 1 and the dosage was gradually increased to 3 gm. daily.

Abscesses and sinuses then began to appear on the left anterior chest wall and the general condition became worse. On May 22, the patient's name was placed on the danger list. The red-cell count was 3,500,000, the hemoglobin 66 per cent, and the white-cell count 22,000, with 86 per cent neutrophils, 7 per cent lymphocytes, 4 per cent monocytes and 3 per cent eosinophils. Sulfanilamide (6 gm.) was given that day. The next day the dose was reduced to 4 gm. From May 24 to June 12 the patient received 3 gm. daily. Abscesses were aspirated on two additional occasions in May and June. Actinomycotic sulfur granules were still present. The patient improved clinically, however, and on June 6 potassium iodide was discontinued. On June 25, her name was removed from the danger list.

The patient's condition during July appeared stationary. Six chest sinuses were still draining. Sulfanilamide (4 gm.

*Superintendent, Norfolk County Hospital, South Braintree, Massachusetts.

†Assistant physician, Norfolk County Hospital, South Braintree, Massachusetts.

daily) was resumed on July 23 and continued until August 15, when sulfathiazole was substituted. This was not tolerated and was discontinued after 2 days. Potassium iodide (2 gm. daily) had been resumed on July 23, and the dosage was gradually increased so that by August 29 the patient was receiving 9.3 gm. daily. Iodides were discontinued on September 13 because of a rash on the chin, but were resumed in gradually increasing doses so that by October 1 10.6 gm. daily was being given. The iodides were continued during the remainder of the hospitalization.

The temperature and pulse showed small but almost daily elevations during the summer, and soreness in the left chest was again noted. Sulfadiazine (4 gm. daily) was begun on September 12. Drainage from the sinuses decreased, and

tuberculosis merely because the common pyogenic organisms cannot be found in the pus. Even in a case such as the present one, where there was a proved antecedent history of tuberculosis, a search should be made for fungi as well as tubercle bacilli and pyogenic bacteria.

Since 1938 at least 5 cases of pulmonary actinomycosis have been reported in which arrest or cure of the disease has been attributed largely, if not wholly, to sulfonamide therapy. The impression

FIGURE 1. General Trends of Temperature, Pulse and Respirations, with Accompanying Therapy.

improvement in the condition was so remarkable that sulfadiazine was discontinued on September 16.

In addition to the iodides, the patient received ferrous sulfate for her anemia and vitamins to supplement the diet. Blood-cell counts and urine examinations were made almost daily. The patient continued to improve and the sinusitis appeared entirely resolved on March 1, 1943, she was discharged.

Figure 1 shows the general trends of the temperature, pulse and respirations during the entire period of illness, as well as the therapy.

At a follow-up examination on January 8, 1944, the patient felt well and had gained fourteen pounds. She denied cough, expectoration or pain. The sinuses had been dry for more than 6 months, and she had been working for 4 months. She was continuing to take 5.3 gm. of potassium iodide daily. A chest roentgenogram was essentially negative except for an area of density in the left base that was apparently due to thickened pleura.

DISCUSSION

Because of its rarity, the diagnosis of pulmonary actinomycosis is frequently missed. Sulfur granules are not always present in the sputum or in the pleural exudate, and even when they are they may not be evident on casual inspection. One must not assume that a chest abscess or empyema is due to

gained from a study of the case reported in this article is that improvement and recovery were definitely enhanced, if not actually brought about, by the use of sulfonamides. Since iodides were also given almost throughout the hospital stay, it is impossible to offer incontestable proof that the sulfonamides alone were responsible for the patient's recovery.

Because iodides in massive doses have been so long regarded as an aid in the treatment of actinomycosis, there is a natural reluctance to abandon them entirely for newer methods of treatment. If iodides are of value at all, their worth is augmented by sulfonamides. It appears likely, however, that sulfonamides are more effective than iodides and may soon replace them entirely in the therapy of actinomycosis.

An interesting side light on this case is that the patient, who had a proved history of tuberculosis, received more than 1800 gm. of potassium iodide in a period of seven months without any evidence of reactivation of the tuberculosis. In an arrested case of tuberculosis iodine should apparently not

PULMONARY ACTINOMYCOSIS

Treatment with Sulfonamides

NAHUM R. PILLSBURY, M.D.,* AND JOSEPH D. WASSERSUG, M.D.†

SOUTH BRAINTREE, MASSACHUSETTS

PULMONARY actinomycosis is uncommon. At the Johns Hopkins Hospital only one case was found in 12,000 consecutive autopsies.¹ The prognosis is poor and most cases end fatally.¹⁻⁵

The treatment of actinomycosis has in general been unsatisfactory. Iodine is the time-honored weapon against this fungus infection, but thymol, roentgen rays, a variety of vaccines and recently sulfonamides have been used. Masson⁶ reported clinical cures in 2 cases of abdominal actinomycosis by roentgen-ray therapy, but, as a rule, roentgen-ray treatments are only partially effective or totally ineffective. Neuber⁷ advocated "specific" vaccines, convalescent serums and autohemotherapy, but his practically 100 per cent cures still lack confirmation.

Several recent reports have stressed the effectiveness of the sulfonamides even when other treatments were at best of only slight benefit. In a case of abdominal actinomycosis, Walker⁸ reported healing three weeks after sulfanilamide was begun and after iodides had apparently proved of no value. Miller and Fell⁹ tried thymol, potassium iodide and roentgen rays, but their patient became progressively worse. Sulfanilamide therapy was instituted and improvement was noted in one week.

Sulfanilamide has also been used in pulmonary actinomycosis. Morton⁴ reviewed a case that failed to improve with 400 gr. of potassium iodide daily and roentgen-ray treatments. He stated that sulfanilamide and promin made a definite improvement in the general condition, whereas potassium iodide, even in massive doses, was of only moderate value. Of several different treatments used by Dobson, Holman and Cutting,¹⁰ sulfanilamide seemed to be the most effective therapeutic agent. Wilkinson¹¹ also obtained good results with sulfanilamide and recommended that it be given for several weeks, if necessary. Temporary benefit was obtained by Schneider and Finucane,⁵ but their patient died of complications resulting from pneumothorax and not from actinomycosis.

Sulfapyridine has been employed effectively in both abdominal and pulmonary actinomycosis. Ogilvie¹² treated a young girl with abdominal actinomycosis by massive doses of potassium iodide, but she failed to improve. Sulfapyridine was then given and the response was so favorable that the drug was discontinued in thirteen days. Mitchell¹³ tried tincture of iodine and oral actinomycotic vac-

cine, with no success. Sulfapyridine brought about prompt healing of sinuses and apparent clinical cure.

The following case of pulmonary actinomycosis is reported not only because of the rarity and seriousness of this disease, but more especially because sulfonamides appeared to be of considerable therapeutic value.

CASE REPORT

T. M. C. a 29-year-old housewife, was first admitted on September 4, 1940, after a chest roentgenogram, taken because of a tuberculous husband, had revealed tuberculosis. The past history disclosed incision of the cervical lymph nodes in 1930 and pleurisy 4 months before admission.

Physical examination was essentially negative except for a scar on the right side of the neck and fine rales in the left axilla. A roentgenogram showed areas of increased density in both lungs at the level of the first anterior intercostal space. The urine was negative. Blood examination revealed slight anemia. The sedimentation rate was increased. A Mantoux test was positive. The sputum was negative for tubercle bacilli, but a gastric specimen was positive by guinea-pig inoculation. On November 11, the patient left the hospital against advice.

On April 1, 1942, the patient was readmitted because of pain and swelling in the left chest wall, fever and marked loss of weight. One and a half months before re-entry she had gone to another hospital because of a pain in the left chest of 1 month's duration. While there, the left pleural cavity was incised and 2 cc. of thick pus was obtained. On re-entry the patient appeared extremely ill, thin and pale. A 2-cm scar was present just below the inferior angle of the left scapula, and a fluctuant hot swelling extended from this point downward to the tenth rib. A roentgenogram of the chest showed a density consistent with fluid in the left intrapleural space and fibrosis in the left first intercostal space. The temperature was 101° F., the pulse 140, and the respirations 28. The urine was negative. The red-cell count was 3,900,000 the hemoglobin 76 per cent, and the white-cell count 10,500. A blood Hinton test was negative. The sputum and gastric contents were negative for tubercle bacilli by concentration and guinea-pig inoculation.

The day following admission, 2 cc. of thick pus was obtained by aspiration of the chest abscess. This pus proved negative for tubercle bacilli by smear, culture and guinea-pig inoculation, but a smear and culture showed *Actinomyces hominis*. Aspiration was repeated on April 10, and 150 cc. of pus containing numerous sulfur granules was obtained. Within the next 2 weeks four sinuses developed at the site of the abscess. In May the patient developed a productive cough, and sulfur granules were found in the sputum. Potassium iodide was begun on May 1 and the dosage was gradually increased to 3 gm. daily.

Abscesses and sinuses then began to appear on the left anterior chest wall and the general condition became worse. On May 22, the patient's name was placed on the danger list. The red-cell count was 3,500,000, the hemoglobin 66 per cent, and the white-cell count 22,000, with 86 per cent neutrophils, 7 per cent lymphocytes, 4 per cent monocytes and per cent eosinophils. Sulfanilamide (6 gm.) was given that day. The next day the dose was reduced to 4 gm. From May 24 to June 12 the patient received 3 gm. daily. Abscesses were aspirated on two additional occasions in May and June. Actinomycotic sulfur granules were still present. The patient improved clinically, however, and on June 6 potassium iodide was discontinued. On June 25, her name was removed from the danger list.

The patient's condition during July appeared stationary. Six chest sinuses were still draining. Sulfanilamide (4 gm

and hernia in scar was markedly less in the transverse group. These writers stress a great diminution in postoperative pain and discomfort. They state that Baudelocque⁴ advocated the transverse approach nearly one hundred and twenty-five years ago, and used it in cesarean section.

Since Pfannenstiel,⁶ in 1900, advocated a transverse approach to pelvic surgery, there have been numerous advocates of some modification of the method to the abdominal cavity in general. Singleton and Blocker⁵ made an exhaustive study of the anatomical approaches to abdominal viscera in relation to wound disruption. Although their incisions were not quite what is interpreted as transverse, they were intended to accomplish much the same purpose. Gurd⁷ has strongly advocated the transverse approach to the exclusion of all others. Farr⁸ has also contributed much to the subject.

The use of transverse incisions has been adopted in some clinics with considerable regularity, whereas in others it has been used sporadically. At the Massachusetts General Hospital it is believed that many lesions are more easily handled through this approach. There are many patients whose wide-flaring costal angle make a transverse incision desirable for lesions of the upper abdomen. In the patient with a narrow, elongated costal angle, better exposure to the upper regions of the abdomen can be obtained through a long paramedian incision. With the use of nonabsorbable suture material, careful avoidance of nerve damage, absence of drainage through the wound, proper closure and the elimination of postoperative distention and vomiting, there will be less choice between the two methods.

Intestinal Trauma

Intestinal trauma during laparotomy has been properly condemned by Martland.⁹ He found the imprints of forceps, used by the surgeon in returning the small intestine to the abdominal cavity, at autopsy in 2 cases. In one case, 1500 cc. of blood that had come from such injuries was found in the lumen of the bowel. In another, he found more than forty of these imprints on the small bowel. In both cases, the surgeon had used a form of intestinal forceps devised for other purposes. They were of the kind that take a wide bite in the intestinal wall, producing a crushing defect that destroys the mucosa and submucosa. Such instruments are of little value for any purpose in intestinal surgery, and should never be used to grasp a segment of bowel that is not to be resected. Since instruments of this type are available, the only safe dictum seems to be to use no instrument in handling the intestine either during exploration or in returning the bowel to its natural position. Better anesthesia and the proper use of gloved hand and abdominal retractors will eliminate the need of a more traumatizing technic.

Drainage of Peritoneal Cavity

Drainage of the peritoneal cavity has been criticized by Cutler.¹⁰ It is amazing that there is still fixed in the minds of many surgeons the belief that the peritoneal cavity can be drained. When there is widespread abnormal fluid within the abdomen, it must be realized that adequate drainage to the outside is almost impossible to establish. The temptation is too great to resist, however, and is apt to lead to the establishment of some variety of foreign body from the depth of the cavity to the periphery. That a certain amount of the fluid contents surrounding the intestines can be led off for a short period of time is acknowledged. That these so-called "drains" not only fail to reduce the incidence of residual abscess but are an extra hazard, in that they form the basis of point obstruction to the bowel by adhesive bands, is obvious to all who have followed the course of these cases.

One does better to remove contaminated or irritating fluids, such as duodenal or gastric contents from acute perforation and bile, when such has escaped widely, by means of the suction tip. Closing the source of the leak is important if this has not already been spontaneously accomplished. In diffuse peritonitis of the inflammatory type seen in perforated appendicitis, one can seldom aid in the recovery by the establishment of drains to the gutters and the pelvis, as is so often practiced. Much can be accomplished by the drainage of a localized abscess or an area where leakage may take place. Care must be used to avoid contact with a suture line or it will leak in a disconcerting manner; also, material used for drainage must not come in contact with the small bowel.

Care should be used to place drains from the biliary system away from the main wound if possible. Needless wound infection, dehiscence and hernia in the scar can thus be avoided.¹¹ The suction method of Chaffin¹² has been used at the Massachusetts General Hospital to hasten the resolution of an abscess cavity. Our experience with this method in bile peritonitis has met with less success. It is, however, a logical method of carrying off the discharges of a fistulous tract and has much to commend it.

Chemotherapy

Chemotherapy is justifiably credited with improving the results in gastrointestinal surgery. Anglem and Clute¹³ believe that it decreased the mortality rate in 75 consecutive cases of resections. They have reduced the amount of the drug used intraperitoneally from about 15 to about 5 gm. They dust the suture line with sulfanilamide powder and use some in the abdominal wall. The use of this method around the suture line has also been approved by Whipple.¹⁴

be withheld for fear of activation of the disease if indications for its use exist.

SUMMARY AND CONCLUSION

A case of pulmonary actinomycosis, in a patient with arrested pulmonary tuberculosis, is reported in which the sulfonamides apparently resulted in a cure.

The sulfonamides appear to be a valuable aid in the treatment of pulmonary actinomycosis, if not actually a specific cure. Iodides seem to be of less value than either sulfanilamide or sulfadiazine.

After this article had been submitted for publication, 2 cases of actinomycosis were reported in which sulfadiazine was the only medication employed.^{14, 15} In both, apparent cure of the disease was attributed to the sulfadiazine.

MEDICAL PROGRESS

ABDOMINAL SURGERY

ARTHUR W. ALLEN, M.D.*

BOSTON

RECENT advances in the field of abdominal surgery are numerous. They will be reviewed under a general heading and under others according to the involved viscus.

GENERAL CONSIDERATIONS

Anesthesia

The use of barbiturates in conjunction with other forms of anesthesia has been a popular development. Preliminary sedation has gradually changed from the morphine-and-scopolamine method toward more reliable and safer drugs. Avertin is being used much less extensively than heretofore, since other agents have proved to be more satisfactory.

In an attempt to determine the value of barbiturates in the reduction or delaying of shock under conditions of trauma similar to war wounds, Beecher, McCarrell and Evans¹ have reported the results of their experiments. In anesthetized animals, barbiturates delay shock from trauma producing dehydration or plasma loss, but not shock from hemorrhage. These authors further state that up to the time of the publication of their paper there were no data available to support the theory that barbiturates delay shock in the unanesthetized patient.

Anderson, Mousel and Mayo² have compared a group of patients operated on for lesions of the colon by two methods of supplementing spinal

anesthesia. When supplementary inhalation anesthesia was used, three times as many patients vomited and there was a 12 per cent mortality rate, whereas in a similar group of patients given a 2.5 per cent solution of Pentothal Sodium intravenously and 100 per cent oxygen by inhalation, only 5 per cent died. The average total amount of Pentothal Sodium given was slightly less than 1 gm. Quick recovery from anesthesia and absence of nausea were believed to play a distinct role in the better results.

This method has been used with and without oxygen at the Massachusetts General Hospital, and there seems to be little difference in the results unless the patient is nauseated early in the procedure. When this occurs, the addition of oxygen is of great benefit. It is probable that the total dose of Pentothal Sodium can be reduced by the use of oxygen, and also that there is a more rapid elimination of the drug. It is extremely desirable to prevent actual vomiting, since inspiration pneumonitis must be avoided. Oxygen inhalation appears to be harmless and probably should be used routinely in this combination.

Transverse Incisions

Transverse incisions are championed by Rees and Coller.³ They compare 225 patients operated on for abdominal lesions through transverse incisions with 346 in whom the vertical approach was used. Pulmonary complications occurred in 9.5 per cent of the transverse group, as compared with 26 per cent in the vertical. The incidence of dehiscence

*Lecturer in surgery, Harvard Medical School; chief, East Surgical Service, Massachusetts General Hospital.

and hernia in scar was markedly less in the transverse group. These writers stress a great diminution in postoperative pain and discomfort. They state that Baudeloque⁴ advocated the transverse approach nearly one hundred and twenty-five years ago, and used it in cesarean section.

Since Pfannenstiel,⁵ in 1900, advocated a transverse approach to pelvic surgery, there have been numerous advocates of some modification of the method to the abdominal cavity in general. Singleton and Bloeker⁶ made an exhaustive study of the anatomical approaches to abdominal viscera in relation to wound disruption. Although their incisions were not quite what is interpreted as transverse, they were intended to accomplish much the same purpose. Gurd⁷ has strongly advocated the transverse approach to the exclusion of all others. Farr⁸ has also contributed much to the subject.

The use of transverse incisions has been adopted in some clinics with considerable regularity, whereas in others it has been used sporadically. At the Massachusetts General Hospital it is believed that many lesions are more easily handled through this approach. There are many patients whose wide-flaring costal angle make a transverse incision desirable for lesions of the upper abdomen. In the patient with a narrow, elongated costal angle, better exposure to the upper regions of the abdomen can be obtained through a long paramedian incision. With the use of nonabsorbable suture material, careful avoidance of nerve damage, absence of drainage through the wound, proper closure and the elimination of postoperative distention and vomiting, there will be less choice between the two methods.

Intestinal Trauma

Intestinal trauma during laparotomy has been properly condemned by Martland.⁹ He found the imprints of forceps, used by the surgeon in returning the small intestine to the abdominal cavity, at autopsy in 2 cases. In one case, 1500 cc. of blood that had come from such injuries was found in the lumen of the bowel. In another, he found more than forty of these imprints on the small bowel. In both cases, the surgeon had used a form of intestinal forceps devised for other purposes. They were of the kind that take a wide bite in the intestinal wall, producing a crushing defect that destroys the mucosa and submucosa. Such instruments are of little value for any purpose in intestinal surgery, and should never be used to grasp a segment of bowel that is not to be resected. Since instruments of this type are available, the only safe dictum seems to be to use no instrument in handling the intestine either during exploration or in returning the bowel to its natural position. Better anesthesia and the proper use of gloved hand and abdominal retractors will eliminate the need of a more traumatizing technic.

Drainage of Peritoneal Cavity

Drainage of the peritoneal cavity has been criticized by Cutler.¹⁰ It is amazing that there is still fixed in the minds of many surgeons the belief that the peritoneal cavity can be drained. When there is widespread abnormal fluid within the abdomen, it must be realized that adequate drainage to the outside is almost impossible to establish. The temptation is too great to resist, however, and is apt to lead to the establishment of some variety of foreign body from the depth of the cavity to the periphery. That a certain amount of the fluid contents surrounding the intestines can be led off for a short period of time is acknowledged. That these so-called "drains" not only fail to reduce the incidence of residual abscess but are an extra hazard, in that they form the basis of point obstruction to the bowel by adhesive bands, is obvious to all who have followed the course of these cases.

One does better to remove contaminated or irritating fluids, such as duodenal or gastric contents from acute perforation and bile, when such has escaped widely, by means of the suction tip. Closing the source of the leak is important if this has not already been spontaneously accomplished. In diffuse peritonitis of the inflammatory type seen in perforated appendicitis, one can seldom aid in the recovery by the establishment of drains to the gutters and the pelvis, as is so often practiced. Much can be accomplished by the drainage of a localized abscess or an area where leakage may take place. Care must be used to avoid contact with a suture line or it will leak in a disconcerting manner; also, material used for drainage must not come in contact with the small bowel.

Care should be used to place drains from the biliary system away from the main wound if possible. Needless wound infection, dehiscence and hernia in the scar can thus be avoided.¹¹ The suction method of Chaffin¹² has been used at the Massachusetts General Hospital to hasten the resolution of an abscess cavity. Our experience with this method in bile peritonitis has met with less success. It is, however, a logical method of carrying off the discharges of a fistulous tract and has much to commend it.

Chemotherapy

Chemotherapy is justifiably credited with improving the results in gastrointestinal surgery. Anglem and Clute¹³ believe that it decreased the mortality rate in 75 consecutive cases of resections. They have reduced the amount of the drug used intraperitoneally from about 15 to about 5 gm. They dust the suture line with sulfanilamide powder and use some in the abdominal wall. The use of this method around the suture line has also been approved by Whipple.¹⁴

Loria¹⁵ has compared the results in 100 consecutive cases of gunshot wound of the abdomen treated at the Charity Hospital in New Orleans. Forty-nine patients received chemotherapy, with a mortality rate of 18 per cent; 51 had no chemotherapy, and 51 per cent of them died.

All writers are in agreement that proper use of the sulfonamide drugs has been beneficial in dealing with surgical lesions prone to give rise to trouble from infection. The manner of use of these agents is changing as experience accumulates. In order to avoid some of the serious complications of the drug, it is well to weigh the evidence carefully. The relatively soluble sulfanilamide is absorbed from the peritoneal cavity with great rapidity. The transmission of large amounts of this drug through the portal system may account for the liver damage often noted. That many patients rapidly recover from jaundice that occurs is admitted, but if this concentration can be avoided it is obvious that the patient has less to combat in his fight for recovery. The less soluble drugs should probably not be used in the peritoneal cavity, since there must be some foreign-body reaction from them before absorption takes place.

The use of these chemical agents in abdominal wounds has met with less enthusiasm than formerly and probably will eventually be entirely abandoned. Although the bacteriostatic effect within the potentially contaminated wound may appear helpful in some cases, there has resulted delayed wound infection that is more troublesome than the earlier form noted before chemotherapy was known. It seems likely that delayed closure of the skin and fat layers, as emphasized by Collier and Valk,¹⁶ is a better method of meeting the situation.

Since it is known that a high concentration can be quickly obtained by the intravenous use of sulfadiazine and that tissue fluids carry essentially the same concentration as that of the blood stream,¹⁷ it seems likely that wide application of the principle is indicated. This method of chemotherapy in abdominal surgery, to the exclusion of all others, has been used at the Massachusetts General Hospital for over a year, and we are better satisfied with the results.

Femoral Hernia

Femoral hernia has been difficult to cure. The recurrence rate in most clinics is several times that for inguinal hernia. Moore¹⁸ reports on the results from the New York Hospital and recommends a new approach. An incision is made over the lower third of the inguinal canal, and dissection is carried deep and to the inferior border of Poupart's ligament. In this manner, the lower borders of the inguinal ligament and Cowper's ligament are adequately exposed. These structures can be approximated with three mattress sutures of silk in such a manner as effectively to close the femoral opening.

In 40 cases thus treated, there were no recurrences.

It is doubtful that the results by this method will prove to be any better than the commonly practiced procedure of closing the femoral opening by approximating the ligaments from the cephalward border of the inguinal ligament. That the new method requires less dissection is obvious, and it may be adopted to advantage by those who prefer to expose the femoral ring only from below.

STOMACH

Gastric Ulcer

Gastric ulcer has been analyzed by Judd and Priestley¹⁹ on the basis of treatment at the Mayo Clinic. They found that slightly less than half the patients treated medically had satisfactory results, whereas only 1 patient of 162 treated surgically was dissatisfied. None of the patients operated on developed anastomotic ulcer. The operative mortality was 2.5 per cent. Ten per cent of the cases diagnosed and treated as benign ulcer proved to be cancer.

This study is in accord with experience at the Massachusetts General Hospital.²⁰ We found our percentage of diagnostic errors to be 14 per cent. The mortality rate for gastrectomy for gastric ulcer is less than that for a similar procedure for duodenal ulcer because the duodenal stump creates no problem. We also found that cancer of the stomach, thought to be ulcer at the time of operation, gave a 40-per-cent chance of a five-year cure, as compared with a 21-per-cent chance in clinical cancer. It is our belief that gastric ulcer must be considered on a different basis than duodenal ulcer, and that the management of the two lesions is quite opposed. Duodenal ulcer is primarily a medical problem, whereas gastric ulcer is primarily a surgical one. If the term "peptic ulcer" could be abandoned, there would be less confusion. Too many cases of early cancer of the stomach are being treated as peptic ulcer, the true nature of the lesion being manifested only when cure is impossible.

Cancer

Cancer of the stomach continues to lead the list for deaths from cancer in this country. Greater attention must be given to the education of the public and of physicians concerning the early symptoms of this disease. So far, surgery offers the only method of cure. In spite of the increased scope of surgery, there still remain a large majority of these victims appearing too late for help.

De Amesti,²¹ of Santiago, analyzed 107 consecutive cases of cancer of the stomach personally treated. He was able to accomplish partial gastrectomy in 43 and total gastrectomy in 9. This is a higher resectability rate than can usually be carried out in such patients seen in the United States.

Pack and McNeer²² have collected 303 cases of total gastrectomy for cancer. The technic is now

well established, and there are undoubtedly hundreds of unreported cases. Members of the staff of the Massachusetts General Hospital alone have done more than 100 total gastrectomies. Eleven of these were high lesions involving the cardia and lower esophagus and were accomplished transthoracically. Many of these appeared unfavorable from the standpoint of nodal involvement and extension of the disease to neighboring structures. The mortality rate is lower than formerly, the extent of the procedure has increased, and the respites have well justified the effort.

Farris, Ransom and Collier²³ followed their patients surviving total gastrectomy from the standpoint of nutrition and hematopoiesis. Five of the 29 patients operated on since 1937 failed to survive the procedure, with only 2 deaths in the last 19. These writers state that there is no experimental evidence to support the clinical impression that pernicious anemia may follow total gastrectomy. They carefully checked the digestion in a woman of forty living for over four years after total gastrectomy. She did have a tendency to develop hypochromic microcytic anemia. The loss of the stomach, it is stated, interferes with the metabolism of iron, and anemia is easily controlled by the periodic administration of ferrous sulfate. The stomach does not play an essential role in the digestion of fat and protein. Glucose is absorbed more rapidly than normal in these patients. The mobility of the intestinal tract is finally decreased in spite of the fact that some of the patients have diarrhea immediately after operation. This is doubtless due to the tendency to feed carbohydrates in the early days. A high-protein and low-carbohydrate diet is recommended.

Balfour²⁴ found that gastrectomized rats did not gain weight on their usual diet. If, however, he fed them rat stomachs, their weight increased and their anemia improved.

Polypoid Lesions

Polypoid lesions of the stomach have been well analyzed by Spriggs and Marxer²⁵ in a complete issue of the British *Quarterly Journal of Medicine*. The differential diagnosis of true adenomatous polyps and polypoid gastritis is illustrated by case reports, drawings and roentgenograms. They include leiomyomatous lesions in their study. Attention is called to the neoplastic nature of true polypoid tumors as compared with the inflammatory origin of polyps found in gastritis. The ratio of malignant degeneration was lower than that found at the Massachusetts General Hospital²⁶ and by Pearl and Brunn.²⁷ The latter investigators, in a second analysis of the subject, have collected 84 cases of multiple gastric polyposis and added 3 cases of their own. In their group, as in ours, bleeding was the rule and achlorhydria was present in almost every case. In 19 of 37 cases with sufficient data, malignant

degeneration had occurred. This is higher than the 41 per cent of malignant degenerations found in our series. Although some of these cases, as well as those reported by Spriggs and Marxer, were followed for many years without evidence of cancer, it is agreed by all that resection of the involved segment is the rational treatment.

DUODENUM

Heuer and Holman²⁸ have challenged the usually accepted theory that the postoperative acid level in the stomach contents influences the result in patients subjected to surgery for duodenal ulcer. They have carefully followed a group of patients treated by gastroenterostomy and minimal, moderate and extensive resection. Many of the cases with a satisfactory result still had an acid level higher than normal. A greater proportion of satisfactory results were obtained by radical subtotal gastrectomy, but the series was small. Patients with anacidity or low acidity postoperatively had a 10 per cent greater chance of a satisfactory result than did those who continued to have a normal or higher than normal level. These writers justifiably question the rationale of the more radical procedures, and believe that there are other factors than the acid level that are responsible for the results.

Friedall, Shaar and Walters²⁹ found that 75 per cent of their patients subjected to partial gastrectomy for duodenal ulcer had a reduction in gastric acidity. Patients who had had previous perforation or had developed anastomotic ulcer following gastroenterostomy needed a more radical resection than did those without complications.

Church and Hinton³⁰ report the follow-up results on 104 cases of gastric resection for ulcer. The majority of these were for duodenal ulcer, although, unfortunately, some were for gastric and marginal ulcer, making deductions difficult. The cases were followed for an average of 2.9 years. The sex ratio was 9 males to 1 female. The ages varied from sixteen to sixty-nine. The average duration of preoperative symptoms was eight years. Sixty-five per cent of the stomach was removed, including the duodenal ulcer. Sixty-six per cent of the patients were cured, 25 per cent were benefited, and 9 per cent were not relieved. Forty-six per cent had no free hydrochloric acid after operation, and some of these were in the unbenefited group.

Hinton³¹ believes that pain persisting in spite of adequate treatment and massive hemorrhage are the chief indications for surgery in duodenal ulcer. Intractability is, in fact, synonymous with unrelievable and persistent pain. He also believes that surgery is indicated in massive hemorrhage, regardless of the age of the patient, if continuous transfusion fails to improve the situation. He thinks that it is important to remove the segment of duodenum containing the ulcer, and has been able invariably

to include the ulcer site in the resection. This experience differs somewhat from that of others.

Lahey and Marshall³² have published an excellent article on the surgical management of duodenal ulcer. Their experience with ulcers in the second and third portions of the duodenum, as well as those with extensive inflammatory involvement, is in accord with that of most surgeons dealing with these lesions. One must be prepared to meet ulcerations of the duodenum that are not safely resectable.

Wangensteen³³ has used the idea proposed by Scrimger³⁴ and Estes³⁵ in closing the denuded antral segment. In 15 cases when he found the involved duodenum unresectable, he used the approved modification of the Finsterer exclusion procedure. After removing the mucosa from the antral segment, he approximated the remaining tissues face to face close to the pylorus by mattress sutures, instead of inverting them in the usual manner. This allowed him to trim away excess of the segment and to make a satisfactory leak-proof closure. He left room for an additional row of sutures along the cut edge, with no attempt at inversion. There were no complications in this series.

Andrus, Lord and Steffko³⁶ have reported their experimental and clinical experience with jejunal transplants to the stomach for the reduction of the hydrochloric acid level. In animals, this procedure was effective in every case. Five patients with duodenal ulcer were recently subjected to this operation, and the immediate results were satisfactory.

Colp and Druckerman³⁷ have used jejunostomy for feeding in 51 patients. These were preliminary in 6 cases and complementary in 38. There were no deaths from the jejunostomy, and these writers are enthusiastic over the benefits derived from it. They state that for this purpose, the pursestring type of jejunostomy is preferable to the Witzel type, which corroborates the opinion held at the Massachusetts General Hospital.

Lynn, Hay and Wangenstein³⁸ have had an unusually high percentage of difficulty from stasis in the duodenal loop following gastrectomy. One patient developed gangrene of the duodenum after resection of the stomach for carcinoma; 3 additional patients succumbed to the toxic effects of this loop, which failed to drain into the jejunum or remnant of the stomach. They devised a two-pronged nasal tube that was introduced into the stomach preoperatively. After the anastomosis is partially done, one prong of the tube is placed in the duodenal and the other in the distal jejunal segment.

Proximal jejunostomy for drainage of the stomach segment has been used at the Massachusetts General Hospital during the past year.³⁹ In 63 cases, this method obviated the need of the Levine tube in all but 3. In these failures, we are sure that the catheter left the stomach segment through the anastomosis and therefore failed to drain anything but duodenal contents. The patients like the method, and no

complications have arisen from its use. A No. 16 French double-eyed catheter is introduced through a pursestring opening in the distal jejunum approximately 15 cm. from the anastomosis. A lubricated stylet aids in its introduction 7 to 10 cm. within the stomach segment. The catheter is brought out through a tiny stab wound in the left side of the abdomen.

SMALL INTESTINE

Hinchey⁴⁰ reports 13 cases of gallstone ileus from the Salem Hospital. A seventy-nine-year-old woman survived two operations at intervals for this type of obstruction.

Wangensteen⁴¹ advises aseptic suction decompression enterostomy at the time of operation for gallstone ileus, and has applied this technic to emptying the small bowel in obstruction from other causes. The revival of the Monks's⁴² method was brought out by Cheever⁴³ several years ago. When the Miller-Abbott tube fails, the technic of Wangenstein has much to commend it. Many patients have been known to succumb to the toxins absorbed from unemptied, obstructed loops of small bowel after release of the obstructing focus.

A further report from the University of Minnesota Hospitals⁴⁴ on small-bowel obstruction emphasizes the importance of having this group of patients treated by special assignment. Their mortality rate has been reduced from nearly 20 to 7.4 per cent in the past year.

Smith and Van Beuren⁴⁵ report the results of treatment in 130 cases of acute ileus treated at the Presbyterian Hospital, New York City, from 1936 to 1939. This makes a consecutive report covering twenty-four years' experience in that clinic by the same authors. The mortality has decreased from 66.6 per cent in 1916-1919 to 23.8 per cent in the last series. Since the Miller-Abbott tube has been available, the mortality in 36 cases was 19 per cent; eliminating 4 deaths from paralytic ileus, there remained a 10 per cent mortality from mechanical obstruction.

Schottenfeld⁴⁶ has collected 275 cases of lipoma of the gastrointestinal tract, including 6 of his own; 56 per cent were in the small intestine, and 30 per cent in the ileum. Intussusception occurred in a large percentage of these. The mortality with intussusception from lipoma was 25 to 30 per cent. Three of his cases were found incidentally at autopsy, and 3 were operated on with recovery.

Gerwig and Stone⁴⁷ report a case of intussusception from a jejunal polyp and call attention to the rareness of polyps of the small bowel in comparison with those of the colon. They quote Lawrence,⁴⁸ who found 4 cases of polyp in both the small and large bowel in 232 cases of gastrointestinal polyposis that came to autopsy.

Keyes⁴⁹ again calls attention to the proper approach to fistulas of the small bowel. The operation

is done through a clean field, leaving a small segment of bowel containing the fistula to be removed later or left alone. This attack has much to commend it and can be made easier if a Miller-Abbott tube can be introduced to the point of the fistula. A second tube inserted in the distal limb is valuable if this can be done, since it makes the identification of the fistulous loop a simple matter.

Ginzburg and Garlock⁶⁰ review 77 cases of regional ileitis treated in their clinic. In 23 cases of ileocolic resection, there were 4 deaths. In 54 patients treated by ileocolostomy for exclusion of the diseased process, there were no postoperative deaths. Two patients in this group finally succumbed to sepsis; and 3 were subjected to late secondary resection of the diseased segment because of continued symptoms. In those having primary resection, 3 developed proximal involvement, whereas in the larger group only 2 acquired new areas of the disease. These writers conclude that exclusion by ileocolostomy is the procedure of choice and that the disease segment may be left alone unless it is a factor in continued disability.

Whipple¹⁴ reports 1 death in 23 ileocolic resections for regional ileitis with the preoperative and postoperative use of the Miller-Abbott tube.

Lahey and Sanderson⁵¹ in their recent article on right colectomy by the modified Mikulicz procedure report 1 fatality in 53 cases of regional ileitis treated by this method.

COLON

Singleton⁵² has written an illuminating article on the blood and lymphatic supply of the large bowel. The high incidence of abnormal blood supply, especially to the distal transverse and splenic colon, is of the utmost importance, particularly since the transverse colon beyond the midline may be devoid of anastomotic vessels from the left colic artery. Resection of this segment is likelier to result in gangrene of the remaining portion of bowel than is that of any other by the usual procedures. For this reason, one cannot depend on the types of operation that either fail to visualize the blood supply or limit the resection to the distal transverse segment.

Whipple¹⁴ believes that the preoperative and postoperative use of the Miller-Abbott tube has materially reduced his mortality in resections of the large bowel. Resections of the right colon for cancer in 16 cases in his clinic, without the aid of intubation, resulted in 3 fatalities, whereas in 41 cases in which the Miller-Abbott tube was used, there were only 4 deaths. From 1933 to 1937, resections in 38 cases resulted in 8 deaths, whereas from 1938 to 1942 there were only 7 deaths in 57 cases of resection. Experience and chemotherapy may have played some role, although most of the credit is given to decompression of the bowel by intubation.

Babcock⁴⁹ has devised new clamps for aseptic anastomosis in gastrointestinal surgery. This is the

so-called "one clamp" method and the instruments are a modification of the Rankin, Stone and Wangenstein varieties used for this purpose. Babcock reports resections in 65 serious and complicated cases—35 of the stomach, with 4 deaths, and 30 of the intestine, with 4 deaths.

Fallis⁵⁴ reports the results in 31 cases of lesions in the lower sigmoid and upper rectum treated by anastomosis after the method described by Dixon.⁵⁵ The operation resulted in 2 deaths, and the complications were not extreme. Preliminary transverse colostomy is recommended. Stricture at the suture line was troublesome in some cases. Dilatation of the stricture was satisfactory in some, but permanent colostomy was finally resorted to in others. Drainage of the area is necessary because the suture line is below the peritoneal floor. Healing in this area is slower than it is in cases of peritonealized bowel.

Smithwick⁵⁶ states that 5 per cent of all people over forty years of age have diverticulosis of the colon. Of 333 patients hospitalized for diverticulitis, 64, or 19 per cent, were treated surgically. The best results were obtained by preliminary transverse colostomy. Resection and anastomosis of the diseased segment was best carried out from three to six months after the defunctioning colostomy.

Schnug⁵⁷ reports 6 cases of acute diverticulitis of the cecum, and collected 32 cases reported in the literature. All were diagnosed preoperatively as acute appendicitis, but in 1 resection was performed on the operator's diagnosis of cancer. Three lesions were removed locally, one was left alone, and one abscess was drained. Schnug believes that these lesions are best treated without surgical drainage or resection. The majority of the patients were under forty years of age. One third of them had had previous attacks. The lesions are usually solitary, and the mouth of the diverticulum can often be palpated through the cecal wall.

BILIARY SYSTEM

Gordon-Taylor⁵⁸ reports experimental data to refute the theory of the sphincter mechanism of the lower end of the bile duct. No circular muscular fibers can be found in this region. Only longitudinal and oblique fibers exist, and these are in the distal portion of the papilla of Vater. The action of these fibers, Gordon-Taylor believes, is partly to retract the papilla and partly to erect or aggregate the villous processes centripetally. By this action, duodenal reflux is prevented and the bile flow controlled. It is well to mention the value of the oblique direction of the duct through the duodenal wall, with overhang of mucosa often, if not always, present.

Gray and Sharpe⁵⁹ call attention to the probability that biliary dyskinesia is caused by remnants of the lower end of the gall bladder or cystic duct that are left during cholecystectomy. Of 44 cases studied, 26 had no residual stones; 7 of these were unrelieved

to include the ulcer site in the resection. This experience differs somewhat from that of others.

Lahey and Marshall³² have published an excellent article on the surgical management of duodenal ulcer. Their experience with ulcers in the second and third portions of the duodenum, as well as those with extensive inflammatory involvement, is in accord with that of most surgeons dealing with these lesions. One must be prepared to meet ulcerations of the duodenum that are not safely resectable.

Wangensteen³³ has used the idea proposed by Scrimger³⁴ and Estes³⁵ in closing the denuded antral segment. In 15 cases when he found the involved duodenum unresectable, he used the approved modification of the Finsterer exclusion procedure. After removing the mucosa from the antral segment, he approximated the remaining tissues face to face close to the pylorus by mattress sutures, instead of inverting them in the usual manner. This allowed him to trim away excess of the segment and to make a satisfactory leak-proof closure. He left room for an additional row of sutures along the cut edge, with no attempt at inversion. There were no complications in this series.

Andrus, Lord and Stefkó³⁶ have reported their experimental and clinical experience with jejunal transplants to the stomach for the reduction of the hydrochloric acid level. In animals, this procedure was effective in every case. Five patients with duodenal ulcer were recently subjected to this operation, and the immediate results were satisfactory.

Colp and Druckerman³⁷ have used jejunostomy for feeding in 51 patients. These were preliminary in 6 cases and complementary in 38. There were no deaths from the jejunostomy, and these writers are enthusiastic over the benefits derived from it. They state that for this purpose, the pursestring type of jejunostomy is preferable to the Witzel type, which corroborates the opinion held at the Massachusetts General Hospital.

Lynn, Hay and Wangenstein³⁸ have had an unusually high percentage of difficulty from stasis in the duodenal loop following gastrectomy. One patient developed gangrene of the duodenum after resection of the stomach for carcinoma; 3 additional patients succumbed to the toxic effects of this loop, which failed to drain into the jejunum or remnant of the stomach. They devised a two-pronged nasal tube that was introduced into the stomach preoperatively. After the anastomosis is partially done, one prong of the tube is placed in the duodenal and the other in the distal jejunal segment.

Proximal jejunostomy for drainage of the stomach segment has been used at the Massachusetts General Hospital during the past year.³⁹ In 63 cases, this method obviated the need of the Levine tube in all but 3. In these failures, we are sure that the catheter left the stomach segment through the anastomosis and therefore failed to drain anything but duodenal contents. The patients like the method, and no

complications have arisen from its use. A No. 16 French double-eyed catheter is introduced through a pursestring opening in the distal jejunum approximately 15 cm. from the anastomosis. A lubricated stylet aids in its introduction 7 to 10 cm. within the stomach segment. The catheter is brought out through a tiny stab wound in the left side of the abdomen.

SMALL INTESTINE

Hinchey⁴⁰ reports 13 cases of gallstone ileus from the Salem Hospital. A seventy-nine-year-old woman survived two operations at intervals for this type of obstruction.

Wangensteen⁴¹ advises aseptic suction decompression enterostomy at the time of operation for gallstone ileus, and has applied this technic to emptying the small bowel in obstruction from other causes. The revival of the Monks's⁴² method was brought out by Cheever⁴³ several years ago. When the Miller-Abbott tube fails, the technic of Wangenstein has much to commend it. Many patients have been known to succumb to the toxins absorbed from unemptied, obstructed loops of small bowel after release of the obstructing focus.

A further report from the University of Minnesota Hospitals⁴⁴ on small-bowel obstruction emphasizes the importance of having this group of patients treated by special assignment. Their mortality rate has been reduced from nearly 20 to 7.4 per cent in the past year.

Smith and Van Beuren⁴⁵ report the results of treatment in 130 cases of acute ileus treated at the Presbyterian Hospital, New York City, from 1936 to 1939. This makes a consecutive report covering twenty-four years' experience in that clinic by the same authors. The mortality has decreased from 66.6 per cent in 1916-1919 to 23.8 per cent in the last series. Gerwig and Stone⁴⁷ report a case of intussusception from a jejunal polyp and call attention to the rareness of polyps of the small bowel in comparison with those of the colon. They quote Lawrence,⁴⁸ who found 4 cases of polyp in both the small and large bowel in 232 cases of gastrointestinal polyposis that came to autopsy.

Keyes⁴⁹ again calls attention to the proper approach to fistulas of the small bowel. The operation

of these patients have lived for twenty years post-operatively. Patients with chronic hemorrhagic purpura who do not respond to conservative therapy should be given the benefit of splenectomy. Also, in acute or fulminating hemorrhagic purpura that does not respond promptly to therapy, splenectomy should be performed before the patient's condition becomes critical. It is important to eliminate infection in the prevention of recurrent purpura. Splenectomy is the treatment of choice in hemolytic jaundice, particularly in children. It is preferable to perform the operation during a remission. In adults, splenectomy is not always necessary.

after a second operation, and the authors question the original diagnosis of cholecystic disease. Complete relief was obtained in 11 of the 24 cases without stones that were followed. In 18 cases of residual stones, the stones were in the common duct in 11 cases, with complete relief in 6 and no relief in 4 of the 10 cases followed. In 7 cases with residual stone in the cystic duct, 6 were followed; 5 patients had complete relief, whereas 1 had none. The common duct was normally dilated in all cases with stones. Duodenal adhesions were frequent. Some patients had a degree of hepatitis and some had pancreatitis. Thirty-five patients had definite inflammation of the remnant of the cystic duct. No mention is made of instrumentation of the papilla of Vater in these cases. Two cases of residual stone in an inflamed cystic duct producing marked symptoms of biliary dyskinesia, which came on years after cholecystectomy, were recently seen at the Massachusetts General Hospital. In both cases, the common bile duct had not dilated normally, as it usually does after cholecystectomy. Both were relieved by the removal of the remnant of the cystic duct and a dilatation of the papilla to 6 mm. In both cases, the papilla was abnormally tight.

Dragstedt et al.⁶⁰ report a new technic for re-establishing continuity between the bile duct and the duodenum. A No. 18 French catheter is inserted in the hepatic duct a distance of 5 cm. This is implanted in the wall of the duodenum, after the method of Witzel, with silk technic. The catheter is then brought through the duodenal wall and led through its lumen and out again at some distance. In this manner, the bile is drained to the outside for ten days and the catheter is then removed. This resulted in a two-year cure in a thirty-five-year-old woman. These writers suggest that a similar procedure can be used in the pancreatic duct following resection of that region for carcinoma.

PANCREAS

The variability in behavior of the pancreatic remnant after experimental ligation of the duct is discussed by Dragstedt.⁶¹ In some animals the pancreas atrophied completely, whereas in others the structure was maintained. In those developing a complete fibrosis, the absence of lipocaic action on digestion was evidenced. Dragstedt proposed and carried out intubation of the duct with a ureteral catheter, which was led through the duodenal wall and out again, draining the pancreatic juice to the outside for a period of time. This he believes might improve the results in partial pancreatectomy for carcinoma.

Whipple⁶² discusses the subject and illustrates his present one-stage procedure for resection of the duodenum and pancreatic head for cancer. The end of the jejunum is anastomosed to the cut end of the bile duct. The cut end of the pancreas is implanted in the side of the jejunum, and the cut end of the

stomach is then anastomosed to the jejunum, end to side.

Phillips⁶³ reports a failure due to difficulty with the end of the pancreas and proposes a method similar to that suggested by Dragstedt and Whipple.

Rockey⁶⁴ cites a case of total pancreatectomy with death fifteen days later from bile peritonitis, owing to a leak from the cut end of the common bile duct. He believes that a patient may get on satisfactorily without any remaining pancreatic tissue, since the insulin needs are easily controlled. Lipocaic can be added to the diet.

SPLEEN

Sweet⁶⁵ adds 3 cases of true simple cyst of the spleen. He quotes Fowler,⁶⁶ who states that 21 per cent of 137 collected cases are of this variety. The differential diagnosis is discussed. All the patients are young and are conscious of a huge abdominal mass. The tumor feels cystic and is nontender. The roentgenograms give a characteristic picture.

Zabinski and Harkins⁶⁷ have collected 177 cases of delayed splenic rupture, including 4 cases of their own. This clinical syndrome, following trauma, is one that should always be considered in the differential diagnosis of the acute abdomen.

McLaughlin⁶⁸ encountered 30 cases of familial hemolytic jaundice during the last five years, and advised splenectomy in 16 because of clinical and laboratory evidence that the disease process was not latent. Thirteen patients who accepted this advice successfully underwent splenectomy. During operation and in the hour following there was a uniform rise in hemoglobin, which averaged 23 per cent. The red-cell counts correspondingly rose during this same period, with an average increase of 1,100,000 cells. Both the hemoglobin and cell readings fell gradually during the next two days and gradually increased to normal by the end of the first postoperative month. The leukocyte count also rose temporarily during splenectomy. There was no recurrence of the hemolytic factor in any of the 13 patients operated on. If hemolytic factors return after splenectomy, McLaughlin deducts that the original diagnosis was incorrect, that overlooked splenic tissue has become active or that hemolymph nodes have hypertrophied and have assumed a hemolytic character.

Eliason and Stevens⁶⁹ review the literature of the last ten years and give a statistical report showing the mortality and life expectancy following splenectomy in splenic anemia, thrombocytopenic purpura and icterioanemia. To this they add a report of 63 personal cases. Splenectomy gives the patient with splenic anemia the best chance for recovery, and the earlier in the disease it is performed, the lower is the surgical mortality and the greater the life expectancy. Eliason believes that splenectomy should be done even in the presence of cirrhosis. The operative mortality is approximately 10 per cent. Some

2 cc. of undiluted Type 18 rabbit serum, which was followed by a severe chill forty minutes later. Sulfadiazine was again administered. During the third week a loud harsh to-and-fro friction rub obliterating the normal heart sounds was heard in the third interspace just to the left of the sternum. The blood pressure was 90 systolic, 45 diastolic, and continued to be low, although the circulation in the extremities appeared to be satisfactory. He looked slightly cyanotic although he had not been given sulfadiazine for four days, during which period the temperature dropped to around 100°F. When the chemotherapy was resumed the temperature rose to 102°F. The pericardial friction rub cleared, although he continued to have chest signs suggestive of consolidation and pleural fluid. Three chest taps, however, were "dry."

During the fourth week, bronchoscopy revealed large amounts of thick sticky greenish-yellow secretion in the left bronchial tree. This was aspirated, leaving a slightly reddened but otherwise normal mucosa. The orifice of the left lower lobe appeared normal. The aeration of this lobe was much improved after aspiration, and it was planned to continue this procedure by means of an inlying rubber catheter in the left main bronchus, which, however, the patient coughed up after fifteen minutes. His condition continued to be poor, and he raised large amounts of thick greenish-yellow material. A chest tap at the third interspace in the left midclavicular line yielded 100 cc. of sticky serosanguineous fluid from which a Type 18 pneumococcus was cultured. On the twenty-sixth day the pulse was paradoxical, with a rate of 140. The apex impulse was diffuse and tic-tac. A diagnosis of pericarditis with effusion was made, and a tap was attempted. No fluid was obtained, and it was thought that the pericardium was thickened. Three days later a roentgenogram of the chest showed practically no air in the left lung field. The right border of the heart was displaced farther to the right, and there were no visible pulsations along the right border with the patient in the horizontal position. A pericardiectomy was performed, with drainage of about 10 cc. of purulent material, which also yielded a Type 18 pneumococcus on culture. A biopsy of the pericardium showed acute and chronic inflammation.

The pericardial drainage continued to be copious, and it was believed that a large amount of chloride was being lost, the blood serum chloride being 86.8 milliequiv. per liter. The serum protein was 3.8 gm. per 100 cc. The patient was given a transfusion of 500 cc. of blood and 2 liters of saline, followed the next day by 500 cc. of plasma. Because of persistent fever, tachycardia and continued purulent pericardial drainage, the sulfadiazine was stopped and 15 cc. of penicillin (7500 units) was placed in the pericardial cavity.

On the thirty-seventh day a rib resection was performed, with drainage of 10 cc. of pus from an

empyema over the apex of the left lung. Because of the difficulty in maintaining adequate electrolyte balance, — the nonprotein nitrogen was 12 mg. per 100 cc., the chloride 98.2 milliequiv. per liter, and the protein 4.9 gm. per 100 cc., — he was given 10 cc. of adrenocortical substance. He was also given a total of 100,000 units of Type 18 anti-pneumococcus rabbit serum without any reaction. The next day he began to fail rapidly; in spite of being kept in an oxygen tent, he remained cyanotic and died the following day, forty days after admission.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES A. JANEWAY:* This case represents an unsolved bacteriologic problem. Here we have a man who from early life was unable to cope with infections that the majority of us could handle fairly readily.

An interesting point is that the patient went to an infirmary within a few hours after an attack of pneumonia began. He had density involving the whole left chest, and that is unusual for ordinary pneumonia in the first day. At such a time one may even have difficulty by x-ray in making out more than a small patch poking out from behind the heart. That to me is the first indication that something was wrong with this boy's lung other than what he came down with at the specific time.

He was treated with sulfadiazine. He apparently had a Type 18 pneumococcus pneumonia, although that is one of the higher types and not necessarily pathogenic. When Type 18 is found on direct typing, however, lobar pneumonia must be identified with this organism unless one can prove something else. He responded to sulfadiazine for seven days and then became worse. It is not a usual situation for someone with lobar pneumonia to be treated for seven days and develop an apparent relapse. This boy's treatment was adequate, so apparently there was something peculiar about the boy. When he was admitted he had a blood diazine level of 3.5 mg. per 100 cc., which is grossly inadequate if that is all he had throughout the course of the pneumonia. One would feel that he had a relapse because of insufficient chemotherapy. There is no question, I believe, that organisms do tend to develop a certain amount of resistance to the sulfonamide drugs. It is important in treating patients with acute infections, once one makes the decision to use chemotherapy, to treat immediately and intensively.

The past history is exceedingly interesting. He had had pneumonia five times within the preceding ten months, which is a most unusual story. I remember one patient, a boy with a nephrotic type of hemorrhagic nephritis, who in the course of two years had eight pneumococcal infections and four of these were due to Type 8. In the present case, the patient had a different lobe involved each time,

CASE 30031

PRESENTATION OF CASE

A twenty-one-year-old college student who was spending a week end at the beach in midsummer awoke at five o'clock one morning, eight days before admission to this hospital, with severe knife-like pain in the left chest. He rapidly became feverish and within a few hours began to cough up rusty sputum. He took a taxi to the college infirmary, where x-ray examinations showed opacity of the entire left lung field. The sputum typing showed a Type 18 pneumococcus. With the administration of sulfadiazine, the pain, fever and discomfort gradually subsided during a period of seven days and then suddenly became worse, when he was transferred to this hospital.

The patient was reported to have had pneumonia five times within the preceding ten months. It was further alleged that a different lobe had been involved on each occasion and that a different type of pneumococcus had likewise been recovered in each of the various episodes.

The past history recorded the onset of mild diarrhea at the age of one and a half years, which persisted essentially without remission until the age of eighteen, when dilute hydrochloric acid was prescribed with complete and permanent relief. At the age of four and a half an adenoidectomy was performed. Two days later he developed a severe attack of pneumonia, and from that time on suffered one or two attacks of pneumonia every year. These were diagnosed sometimes as lobar and sometimes as lobular in type. At thirteen he had an attack of pansinusitis, when the gastric hypochlorhydria was discovered. At nineteen he had an attack of mild prostatitis that was persistent and failed to respond to sulfanilamide and massage.

The family history revealed that one grandmother was asthmatic.

Physical examination on entry was sketchy because of the patient's condition. The facies appeared anxious and drawn. He was in obvious distress, with labored grunting respirations and com-

plete splinting of the left side of the chest. There were patchy dullness and bronchial breathing in the upper portions of the left chest; over the area of the left lower lobe there were dullness and absent breath sounds. The heart was not enlarged, and there were no murmurs; the pulmonary second sound was greater than the aortic. The abdomen was flat and soft, and no masses or tenderness were made out. The mucous membranes and nailbeds did not appear cyanotic.

The rectal temperature was 103°F., the pulse 120, and the respirations 30.

An x-ray film of the chest taken with a portable machine the day after entry showed the following: "There is hazy density occupying the lower half of the left lung field. The left diaphragm is elevated, and the heart and mediastinum are not displaced. The right lung field is clear. Comparison with a film taken several days before at the college infirmary shows considerable clearing." The following day fluoroscopy showed a triangular area of density involving the midportion of the left lower lobe, which was interpreted as either atelectasis or fluid. Another film from the infirmary, taken four months before entry, after clinical recovery from his last attack of pneumonia, showed incomplete expansion of the left lower lobe.

Laboratory studies at the time of entry showed a hemoglobin of 13.0 gm. and a white-cell count of 14,800, with 75 per cent neutrophils. The urine had a specific gravity of 1.010 and contained no albumin or sugar; the sediment was free from red cells, crystals and casts. A blood Hinton test was negative. The blood sulfadiazine level was 3.5 mg. per 100 cc. Three sputum examinations showed alpha-hemolytic streptococci but no pneumococci. Two blood cultures were negative. The sulfadiazine dosage was increased to 6 gm. per day, and a blood level of 6.2 mg. per 100 cc. was obtained. On this regime the temperature fell to normal on the fourth day and, with one exception, remained normal for six days, the sulfadiazine having been stopped on the fourth day of normal temperature. Physical examination showed complete clearing of the upper lobe and improved aeration of the lower lobe.

On the eleventh hospital day the patient complained of sharp inspiratory pain over the anterior left rib margin and a sensation of chilliness. The temperature rose to 101°F, the pulse from 80 to 110, and the respirations from 20 to 30. There was no change in physical signs, however, and an x-ray film taken with a portable machine was interpreted as showing improvement since the last examination. A sputum examination showed mucopurulent material without blood staining, and from it a Type 18 pneumococcus was grown in pure culture. A few days later, however, a roentgenogram showed a marked change — the development of hazy density obscuring the entire left lung field. After a negative conjunctival serum test, the patient was given

*On leave of absence

cc. of undiluted Type 18 rabbit serum, which was followed by a severe chill forty minutes later. Sulfadiazine was again administered. During the third week a loud harsh to-and-fro friction rub obliterating the normal heart sounds was heard in the third interspace just to the left of the sternum. The blood pressure was 90 systolic, 45 diastolic, and continued to be low, although the circulation in the extremities appeared to be satisfactory. He looked slightly cyanotic although he had not been given sulfadiazine for four days, during which period the temperature dropped to around 100°F. When the chemotherapy was resumed the temperature rose to 102°F. The pericardial friction rub cleared, although he continued to have chest signs suggestive of consolidation and pleural fluid. Three chest taps, however, were "dry."

During the fourth week, bronchoscopy revealed large amounts of thick sticky greenish-yellow secretion in the left bronchial tree. This was aspirated, leaving a slightly reddened but otherwise normal mucosa. The orifice of the left lower lobe appeared normal. The aeration of this lobe was much improved after aspiration, and it was planned to continue this procedure by means of an indwelling rubber catheter in the left main bronchus, which, however, the patient coughed up after fifteen minutes. His condition continued to be poor, and he raised large amounts of thick greenish-yellow material. A chest tap at the third interspace in the left midclavicular line yielded 100 cc. of sticky serosanguineous fluid from which a Type 18 pneumococcus was cultured. On the twenty-sixth day the pulse was paradoxical, with a rate of 140. The apex impulse was diffuse and tic-tac. A diagnosis of pericarditis with effusion was made, and a tap was attempted. No fluid was obtained, and it was thought that the pericardium was thickened. Three days later a roentgenogram of the chest showed practically no air in the left lung field. The right border of the heart was displaced farther to the right, and there were no visible pulsations along the right border with the patient in the horizontal position. A pericardiectomy was performed, with drainage of about 10 cc. of purulent material, which also yielded a Type 18 pneumococcus on culture. A biopsy of the pericardium showed acute and chronic inflammation.

The pericardial drainage continued to be copious, and it was believed that a large amount of chloride was being lost, the blood serum chloride being 86.8 milliequiv. per liter. The serum protein was 3.8 gm. per 100 cc. The patient was given a transfusion of 500 cc. of blood and 2 liters of saline, followed the next day by 500 cc. of plasma. Because of persistent fever, tachycardia and continued purulent pericardial drainage, the sulfadiazine was stopped and 15 cc. of penicillin (7500 units) was placed in the pericardial cavity.

On the thirty-seventh day a rib resection was performed, with drainage of 10 cc. of pus from an

empyema over the apex of the left lung. Because of the difficulty in maintaining adequate electrolyte balance, — the nonprotein nitrogen was 12 mg. per 100 cc., the chloride 98.2 milliequiv. per liter, and the protein 4.9 gm. per 100 cc., — he was given 10 cc. of adrenocortical substance. He was also given a total of 100,000 units of Type 18 anti-pneumococcus rabbit serum without any reaction. The next day he began to fail rapidly; in spite of being kept in an oxygen tent, he remained cyanotic and died the following day, forty days after admission.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES A. JANEWAY:* This case represents an unsolved bacteriologic problem. Here we have a man who from early life was unable to cope with infections that the majority of us could handle fairly readily.

An interesting point is that the patient went to an infirmary within a few hours after an attack of pneumonia began. He had density involving the whole left chest, and that is unusual for ordinary pneumonia in the first day. At such a time one may even have difficulty by x-ray in making out more than a small patch poking out from behind the heart. That to me is the first indication that something was wrong with this boy's lung other than what he came down with at the specific time.

He was treated with sulfadiazine. He apparently had a Type 18 pneumococcus pneumonia, although that is one of the higher types and not necessarily pathogenic. When Type 18 is found on direct typing, however, lobar pneumonia must be identified with this organism unless one can prove something else. He responded to sulfadiazine for seven days and then became worse. It is not a usual situation for someone with lobar pneumonia to be treated for seven days and develop an apparent relapse. This boy's treatment was adequate, so apparently there was something peculiar about the boy. When he was admitted he had a blood diazine level of 3.5 mg. per 100 cc., which is grossly inadequate if that is all he had throughout the course of the pneumonia. One would feel that he had a relapse because of insufficient chemotherapy. There is no question, I believe, that organisms do tend to develop a certain amount of resistance to the sulfonamide drugs. It is important in treating patients with acute infections, once one makes the decision to use chemotherapy, to treat immediately and intensively.

The past history is exceedingly interesting. He had had pneumonia five times within the preceding ten months, which is a most unusual story. I remember one patient, a boy with a nephrotic type of hemorrhagic nephritis, who in the course of two years had eight pneumococcal infections and four of these were due to Type 8. In the present case, the patient had a different lobe involved each time,

*Assistant professor of pediatrics, Harvard Medical School.

and with a different type of pneumococcus. One must assume that there was something obviously wrong in that he was unable to resist infection with the pneumococcus. That is an unexplainable situation, so far as I know, in terms of present bacteriologic knowledge, but it is not too uncommon a story. Some persons have furuncles and develop a generalized staphylococcal infection with osteomyelitis. Others are prone to repeated occurrences of lobar pneumonia, and then there is the group best exemplified by children with rheumatic infection, who are constitutionally unable to handle infection with the hemolytic streptococcus. When we go into the past history of this boy we know that he had an attack of mild diarrhea at one and a half years and that this continued until the age of eighteen, when he was given hydrochloric acid. That again suggests some sort of constitutional defect, because hypochlorhydria or achlorhydria is not common at that time of life and perhaps represents a true functional deficiency of the stomach.

This patient's troubles began at four and a half years, when his adenoids were removed. Two days later he developed pneumonia, and from then on had one or two attacks a year. These were diagnosed sometimes as lobar and sometimes as lobular in type, which does not matter; presumably they were pneumococcal infections, although we do not know. At thirteen he had an attack of pansinusitis, another common form of pneumococcal infection, although it might have been streptococcal. At nineteen he had prostatitis, which was persistent and failed to respond to sulfonamides and massage. This is not at all unusual in patients prone to repeated attacks of upper respiratory infection, and no one can say to what it is due. But all these things point to a person who has a low resistance to infection in general, and particularly to infection in the respiratory tract caused by the pneumococcus.

On entry there were dullness and absent breath sounds in the left lower lobe, and x-ray examination showed hazy density of the lower half of the left lung field, with elevation of the diaphragm on the left. This is in contrast to the picture taken on entry to the infirmary, when he had density involving the whole chest. One is forced to the conclusion that something was wrong with the left lower lobe. Perhaps the process in the upper part of the chest had cleared on sulfadiazine therapy.

May we see the x-ray films?

DR. GEORGE W. HOLMES: To discuss these films completely would take the whole hour. The patient had repeated attacks of pneumonia, and one wonders whether or not there was some trouble in one of the bronchi. Apparently someone else thought of that, since lipiodol was injected into the bronchi. From this film I cannot say definitely that he had or had not any trouble with the bronchi. It is not the usual picture of bronchiectasis; yet it is not quite normal.

Another thing that is fairly striking about the case is that the heart shadow became progressively larger. Whether he developed fluid in the pericardium or whether the change was due to long-standing intrapulmonary pressure, I cannot tell. Another unusual thing is the development of this density, which includes the entire lung. There is no evidence that the mediastinum was displaced or that the heart was pushed to the right.

DR. JANEWAY: Do you not believe that the heart was being pushed to the left?

DR. HOLMES: I cannot answer that definitely, but my feeling is that there was no change in the position of the heart and mediastinum.

Another point is that the process extends to the extreme apex, which is unusual in the presence of fluid. It is seen, however, with complete consolidation of the lung or with tumor. This process comes and goes, and that is hard to explain. Fluid to that extent should displace the heart in the opposite direction. I should think that this was consolidation.

DR. JANEWAY: I think that one can skip through the remainder of this patient's course fairly rapidly. He entered the hospital, as I have said, apparently with considerable change from the first film to the second. Probably the most satisfactory explanation is that he had pneumonia involving the upper portion of the lung. He was treated with sulfadiazine, and most of the process cleared; but a residual was present in the lower lobe, where there were dullness and diminution of the breath sounds. Another thing that strikes me on looking at these films is the contrast between the rib shadows on the two sides; they are drawn closer together on the left than they are on the right. One does not see that in this film, which suggests that later on there was some collapse of the left lower lobe. By increasing the dose of sulfadiazine in a fairly short time the temperature was again brought down and there was clearing of the picture. Therefore, one must assume that because of insufficient therapy he had a relapse of pneumonia, which brought him to the hospital. Although more intensive chemotherapy aborted the infection, it obviously did not cure the patient.

From then on the story is that of someone with complications of pneumococcal pneumonia. After several days of normal temperature he had a second return of symptoms. There were inspiratory pain, pleural pain over the left rib, chills and a rise in temperature, with no change in physical signs. As one watches the course, it seems likely that this was a different sort of relapse from the first one, which was perfectly compatible with a relapse of the pneumonia. This time, I believe, purulent complications were beginning to develop in the left chest, because, from then on, sulfadiazine therapy was relatively ineffectual.

During the third week the patient had a to-and-fro friction rub, with a fall in blood pressure and slight cyanosis. This was accompanied by en-

argument of the heart, as Dr. Holmes has pointed out. There was not the slightest doubt that this boy had pericarditis, which, as you all know, is one of the most serious complications of lobar pneumonia, and formerly occurred in a fair percentage of cases. Here is a boy with almost no resistance to organisms who, in the presence of not too effective chemotherapy, went on to develop some type of purulent complication. An attempt was made to give serum therapy; possibly that should have been done earlier because obviously the boy did not handle pneumococcal infection too well. We do not know whether he had antibodies at the time the serum was given. Presumably he did or he would not have shown much in the way of focal complications. Another factor is that at that time the temperature went up when he was given sulfadiazine and stayed up when it was taken away. As a result of chemotherapy this boy had become sensitive to sulfadiazine, which further complicates the picture.

Another complication was present; this patient eventually had a rib resection because of an empyema, which was evidenced by the aspiration of a sticky purulent secretion, containing a Type 18 pneumococcus, from the region of the left lower lobe.

Perhaps the only intelligent way to put this all together is to say that there was some abnormality that rendered the left lower lobe peculiarly vulnerable, but this vulnerability to pneumococcal infection was probably on the basis of something constitutional, because the patient had had infections everywhere. Another point is that for some reason, possibly because of the development of a small abscess or because he developed a real bronchial occlusion as suggested by the pulling together of the ribs on the left side, chemotherapy, when given to him the first time, perhaps inadequately, failed to cure the infection. There is little question that there was some occlusion on the left because the bronchus contained sticky secretion, and because the infection in the left lower lobe never cleared up. Whether he had bronchiectasis, abscess or an unresolved pneumonia that flared up when the sulfadiazine level fell, I cannot tell.

I should say that at autopsy they found not only empyema and pericarditis but also pneumococcal infection in the left lower lobe, probably some bronchial constriction and therefore abscesses or some fibrosis and collapse. Why the boy died when he did I do not know, but I suspect that it was due either to the pericarditis or to the empyema, which did not respond to drainage. Possibly the infection broke into the peritoneum and produced peritonitis, but I doubt that.

Dr. JOHN CASS: I attended this boy during the week before he came in here and there was no doubt in my mind that he was having another one of his series of acute pulmonary infections, with an underlying disease of a chronic nature. He did quite well for a few days, and then his lungs filled up again and

he was admitted to this hospital. The day before he had had a blood sulfadiazine level of 8 mg. per 100 cc. The next morning the level was 3.6 mg., and we pushed the dose up until it reached a peak of 13 mg. He had an essentially normal temperature for three days except for one time when the sulfadiazine was stopped. At a level of 5 or 6 mg., he flared up again, and we immediately gave more sulfadiazine and kept him at a level of around 8 mg. for the next week. Then, the chest signs changed definitely overnight, an area of complete consolidation appearing. This same thing had happened in one of his previous attacks, when he had flared up overnight with consolidation of the left upper lobe.

The important thing was to get this boy over the acute disease. We all recognized that he had underlying chronic pulmonary disease, presumably bronchiectasis. We did everything that we could. We gave serum when he flared up again under sulfadiazine. He had a severe chill and was pulseless for a few minutes. With the first chill the temperature went up to 106°F., but the next day it fell down and stayed down for two days; then it started to go up again. Dr. Maxwell Finland saw him, and the question was raised whether to give serum again and stop the sulfadiazine. He had seen the boy several times during the previous year. He was not impressed with the Type 18 pneumococcus as the etiologic agent. We again tried sulfadiazine, bringing up the level as high as before, over 10 mg., without any effect. We pushed the sulfadiazine level higher by giving the drug intravenously, gave more serum and drained the empyema and the pericarditis. The chest signs did not change materially, and we believed that one lung was free of infection.

The patient died in a state of anoxemia. He was blue and that was the thing that made us realize that we were not dealing with a unilateral disease. He was cyanotic at all times except for three or four hours after the bronchoscopy, when air got into the lower left lobe for a few hours. We did not have the courage to subject him to bronchoscopy again. He was given oxygen and a mixture of helium and oxygen both by mask and by tent. Our diagnoses were the same as those of Dr. Janeway; we believed that the boy died of lobar pneumonia, with empyema, pericarditis and an underlying chronic diffuse pulmonary disease, probably bronchiectasis.

Dr. JANEWAY: Did he have a reaction the second time serum was used?

Dr. CASS: No.

CLINICAL DIAGNOSES

Lobar pneumonia (Type 18 pneumococcus).
Pericarditis.
Empyema, left.
Bronchiectasis: left lower lobe?

DR. JANEWAY'S DIAGNOSES

Lobar pneumonia (Type 18 pneumococcus): left upper lobe.

Pericarditis (Type 18 pneumococcus).

Empyema, left (Type 18 pneumococcus).

Bronchial constriction and atelectasis, with infection (Type 18 pneumococcus): left lower lobe.

ANATOMICAL DIAGNOSES

Bronchiolitis fibrosa obliterans.

Bronchopneumonia.

Bronchiectasis, left lower lobe.

Pericarditis, acute, fibrinopurulent.

Empyema, left.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: At autopsy this man still had 10 to 15 cc. of pus in the pericardial cavity and some empyema. At the base of the drainage tube, over the visceral pleura, was a huge pocket of

ference, so that there was definite bronchiectasis in the left lower lobe. The right lung, although not collapsed, was also encased in a thick fibrous pleura and on section showed a similar sprinkling of tubercle-like lesions throughout all lobes.

On microscopical examination of the left lung we found that the bronchioles were filled with exudate and that the walls were destroyed in places. There was also a great deal of organization of the exudate within the bronchi and bronchioles, especially in the smaller air sacs or alveolar ducts (Fig. 1). Immediately surrounding the bronchi there was evidence of recent infection. This reminded us of a condition called "bronchiolitis fibrosa obliterans," which was described by Lange¹ in 1901 and again fifteen years ago here in Boston by Blumgart and MacMahon.² The latter described 5 cases which simulated miliary tuberculosis but in which, of course, there was no evidence of tuberculosis. We were able to find similar bronchiolitis with fibrous-tissue plugs in the right lung, with a more acute pneumonic process around

FIGURE 1. Photomicrograph Showing Bronchiolitis Fibrosa Obliterans of an Alveolar Duct.

pus. The left lung was encased in a fibrous pleural capsule 1 to 2 mm. in thickness, and the whole lung itself was shrunken to about two thirds its normal size. On sectioning the lung there were numerous grayish granular foci 1 to 2 mm. in diameter that looked like miliary tuberculosis, and at the time of autopsy the diagnosis lay between tuberculosis and lobar pneumonia with small abscesses. In the left lower lobe the larger bronchi were filled with thick, tenacious material so that it would have been quite impossible for air to get through. The smaller bronchioles were also filled with this material and were distended to perhaps 0.5 cm. in circum-

the bronchi. The disease on the right seemed to be definitely more recent than that on the left, but the fundamental chronic process was the same.

The question arises whether this was the result of an organizing pneumonia and something that he had had for a long time or whether it was the disease entity that had precipitated the attacks of pneumonia. We have seen the same condition a number of times. This morning I looked through our files and found that we have made the diagnosis of bronchiolitis fibrosa obliterans seventeen times. It is interesting that in 5 of the 17 cases the patients had heart disease. Two of these were rheumatic in

origin, which is interesting in view of the fact that an organizing bronchiolitis has been described as a form of rheumatic pneumonia by Masson et al.³ The other 12 cases were associated with pneumonia, organizing pleuritis, empyema or pericarditis, 2 of them occurring in patients with nephritis. Perhaps this is not a disease entity in itself but a nonspecific finding that develops with a diffuse organizing pulmonary infection caused by a variety of etiologic agents. For example, the pulmonary complications of the victims of the Cocoanut Grove fire who died after admission into the hospital showed an acute necrotizing bronchiolitis.⁴ Those who had severe pulmonary damage and survived may well have developed varying degrees of bronchiolitis fibrosa and perhaps will be relatively nonresistant to future pulmonary infections.

In the later stages of the disease, failure of the right side of the heart may occur. This was true in the present case, the right ventricular wall being twice its normal size. There was no evidence of disease in any other organ.

DR. JANEWAY: If you assume this was a chronic process and not one that began with this particular infection, how can you reconcile that with so little change in the earlier x-ray films?

DR. HOLMES: I do not know exactly how much these cases of the type described show on x-ray, but I should certainly say that these films showed nothing abnormal except for the character of the lipiodol shadow in the left descending bronchus. That is abnormal, but it is not characteristic of bronchiectasis.

DR. CASTLEMAN: The right lung was encased in a thickened pleura that certainly antedated the recent disease.

DR. ALLAN BUTLER: If the patient had had bronchiolitis fibrosa obliterans previous to the last attack, then I should think that decreased aeration of the lung would have been noticed clinically and that he would have complained between times of dyspnea.

DR. CASS: He had not been well since he was four years old. The only exception to that was the three years spent in Arizona, and he was not active out there. He never completed a full year of school and really never did anything, just lived the life of an invalid. The first time I saw him he was cyanotic.

DR. JANEWAY: How about the kidneys?

DR. CASTLEMAN: They were normal.

CASE 30032

PRESENTATION OF CASE

A fifty-four-year-old clerical worker entered the hospital because of "asthma" of three weeks' duration.

The patient was in good health until five months before admission, when she developed a severe steady pain in the lower sternum associated with and aggravated by an "awful" nonproductive cough. These continued for two to three weeks. About two months before admission she coughed up frothy white material flecked with blood for three days. She developed a "severe strain" between the scapulas. An x-ray film of the chest was said to have shown "adhesions between the lung and the diaphragm, clearing pneumonia and thickening of the pleura." She remained at home for six weeks without any relief. In the meantime her appetite declined and she developed abdominal and lower costal pain which she attributed to continuous coughing. Three weeks before entry she developed wheezing respirations and a filled-up feeling, in addition to the cough and pain. The cough was productive of a slightly odorous white froth with no thick exudate. The "asthma" improved slightly and the chest pain subsided. There was no fever, chills or night sweats, sinus pain, toothache, sore throat, hay fever or hives. She had had no upper respiratory operations, and there was no history of aspiration of a foreign body. The weight had remained constant until the three weeks before entry, when she had lost about 7 pounds. There was no history of a tuberculous contact.

Physical examination showed a well-developed, well-nourished, slightly dyspneic woman in no distress. There was no nasal obstruction. The "tonsillar nodes" were slightly enlarged and nontender. The diaphragm was in normal position and showed slight mobility. In the lungs there were scattered coarse, sticky rales, a few moist rales and rare sibilant rhonchi. The heart was normal. Examination was otherwise not remarkable.

The blood pressure was 120 systolic, 90 diastolic. The temperature was 98.6°F., the pulse 120, and the respirations 26.

Examination of the blood showed a red-cell count of 4,860,000. The white-cell count was 11,600, with 86 per cent neutrophils. The urine was negative. The blood sedimentation rate was 2 mm. in fifteen minutes and 22 mm. in sixty minutes. A blood Hinton test was negative.

X-ray examination of the chest showed a generalized increase in the lung markings, with diffuse haziness over the lower two thirds of the right chest and to a lesser degree of the left chest. A grid film revealed numerous small areas of diminished density having the appearance of bronchiectatic clanges. The right diaphragm was adherent anteriorly. The

heart was not grossly enlarged. The aorta was tortuous and displayed calcification of the arch.

For the first few days she experienced considerable respiratory distress. She was orthopneic and wheezed heavily. There was no relief from adrenalin, but a certain amount of temporary relief from aminophyllin. She was given 1 gm. of sulfadiazine on the third day, followed by 2 gm. daily for the next six days. On the fifth day the blood sulfadiazine level was 3.8 mg. per 100 cc.

Bronchoscopy on the eighth day showed marked spasm of the vocal cords. The trachea was narrowed in the anteroposterior direction. The carina was thickened and shortened in the anteroposterior diameter, giving it a twisted rope-like appearance. The right bronchus was also narrowed in the anteroposterior diameter and had a similar appearance, which was thought to be due to spasm. On the medial wall of the right main bronchus close to the carina there was a thickening of the bronchial wall that bled easily. A biopsy was attempted but no tissue could be obtained. The left main bronchus had much the same narrowed spastic appearance as the right.

Following bronchoscopy the patient became slightly more dyspneic and cyanotic. Bronchography had to be omitted. She was given 10 cc. of aminophyllin with temporary relief. In the next twenty-four hours she experienced considerable respiratory distress and raised large amounts of blood-tinged, frothy sputum. The respirations were 36, the pulse 140, and the blood pressure 140 systolic, 90 diastolic. On the ninth day coarse rattles were heard over the left chest and the patient was pale, sweaty and cold. The administration of aminophyllin was ineffective, and oxygen gave only temporary relief. She became progressively more dyspneic and died suddenly on the tenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. PAUL C. ZAMECNIK: The first problem to decide in reaching a diagnosis in this case is whether the disease involving the bronchial tree was intrinsic or extrinsic in origin. Since both the right and left main stem bronchi presented the same narrowed, spastic appearance, and inasmuch as both sides of the chest showed diffuse haziness by x-ray,—even though it was more marked in the right chest,—the evidence points toward intrinsic disease of the bronchi and bronchioles.

An extrinsic mediastinal mass would, in general, be more likely to produce bronchial stenosis unilaterally rather than bilaterally. It is true that lymphomatous mediastinal nodes can produce bronchial obstruction of both sides of the chest, but lymphomatous masses of this magnitude are usually visible by x-ray, and in this case no mediastinal enlargement is reported. Such additional possibilities as a dermoid cyst, a neurofibroma, a substernal

thyroid gland, and an enlarged thymus fall into this category and therefore have no positive evidence to support them. In connection with the possibility of aortic aneurysm, the x-ray definition of the aorta with its tortuosity and calcification seems sufficiently clear to make this diagnosis unlikely. Furthermore, the aortic second sound was presumably intact, and the Hinton reaction negative.

A discussion of intrinsic diseases involving the bronchial tree may properly be introduced by a consideration of bronchial asthma and bronchiogenic carcinoma. Against the diagnosis of bronchial asthma are the age of the patient at the onset of the disease, the lack of a previous history of asthmatic attacks, the failure of response to epinephrin, and the rapid, downhill progress of the disease. The spasm of the bronchi and the bronchiectasis, however, fit in well with this diagnosis. It is impossible to rule out bronchiogenic carcinoma, but the bilateral character of the disease and the absence of visible neoplasm by bronchoscopy rob this diagnosis of its chief support.

If this line of reasoning is correct, one is left with certain rarer diseases involving the trachea, bronchi and bronchioles. Scleroma is usually a more chronic type of disease than the one here presented, starting with a falling in and a fibrous-tissue replacement of the cartilaginous framework of the nose and throat; then the glottis and trachea are involved and the process extends downward in the respiratory tract. There is no such antecedent history in this case, and indeed the history suggests that the difficulty progressed upward from the lower part of the respiratory tract.

Most of the data are consistent with a disease in which connective tissue grows in from the walls of the terminal and even the larger bronchi, with a resultant partial or complete occlusion of their lumens. Such a condition occasionally follows pneumonia or acute bronchitis, and is characterized by a progressively downhill course, with dyspnea, orthopnea, cough and fatal termination. In most cases of bronchiolitis fibrosa obliterans, miliary nodules resembling those of tuberculosis are seen in the lung fields by x-ray, but in the present case no mention of such findings is made. In spite of the absence of this valuable sign, I find myself forced to make this diagnosis. The initial chest pain may be attributed to pleural adhesions accompanying the pneumonia, and the remainder of the picture appears to have been due to obliterative bronchiolitis and bronchitis, with bronchiectasis.

CLINICAL DIAGNOSIS

Bronchial asthma.

DR. ZAMECNIK'S DIAGNOSIS

Bronchiolitis fibrosa obliterans.

ANATOMICAL DIAGNOSIS

Carcinoma of pancreas, with metastases to lungs, pleura and bronchial, mediastinal and retroperitoneal lymph nodes.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: This case is another example of Dr. Rackemann's frequent statement "All is not allergy that wheezes," and Dr. Amechnik wisely discarded the diagnosis of bronchial asthma, although that was the ante-mortem diagnosis. There was disease of the bronchial tree, but it

was primarily extrinsic. The autopsy showed diffuse carcinomatosis of both lungs, and microscopically the tumor cells involved the lymphatics, especially in the peribronchial and peribronchiolar lymphatics. In some places tumor cells had extended through the bronchiolar walls and had invaded the mucosa. We were unable, however, to find any gross evidence of a tumor that involved the lumen of a bronchus, and we did not believe that the primary tumor was in the lung. We found metastases in the bronchial and retroperitoneal lymph nodes and finally discovered the primary tumor in the body of the pancreas.

MUTATIS MUTANDIS

CHANGE begets change. Not so long ago it was generally accepted that unconsciousness following a blow on the head — concussion — and the more serious pathologic changes often associated with it were the direct result of the local application of force. This did not explain, however, the damage to the brain opposite the point struck. Because this damage was usually severer than that occurring immediately beneath the point of contact it could not be ignored, and the theory of contracoup was evolved to explain its presence. It was conceded that acceleration or deceleration of the head was necessary to produce the contracoup effect but did not necessarily cause unconsciousness. More recent work done with greater exactness under experi-

mental conditions has also included acceleration or deceleration of the head as a prerequisite of unconsciousness. As a corollary to this point of view the failure to lose consciousness following perforating wounds of the skull, wounds made by multiple small missiles with low velocity or a crush of the head was alleged to be traceable to an absence of acceleration or deceleration of the skull and its contents. These conclusions have been rather widely accepted and they have been regarded as a satisfactory and probably a final explanation of the mechanism of concussion and its associated brain pathology.

Now comes a physicist, a Doctor of Philosophy from Oxford and the holder of an M.A. degree from Edinburgh, who, working as a research physicist in the Laboratory of Physiology and the Department of Surgery at Oxford, propounds a new explanation for the development of unconsciousness and the causation of all degrees of brain injury.* In the course of his paper he claims that neither the contracoup nor the acceleration-deceleration effect is adequate as explanation for such results. He states that the most important physical properties of the brain are its comparatively uniform density, its extreme incompressibility, the small resistance it offers to change in shape as compared with the skull which it offers to change in size (the effect of pressure by a retractor as compared with that of an estimate pressure of 10,000 tons), and the lesser rigidity of the brain as compared with that of the skull — 1 ton being required to reduce the diameter of the skull by 1 cm. Furthermore, he asserts that the shapes of the skull and brain determine the location of the injuries. He also points out that if one grants that the brain behaves like similar substances whose physical properties have been studied to date, its constituent particles are pulled so far apart as the result of a blow that they do not join up again properly when the immediate effect of the blow is over. The amount of this pulling apart is proportional to shear strain or rotational effect, and not to the amount of compression that occurs.

In conformity with this conception and working with a model constructed of materials that are claimed to react to blows in the same way that the skull and brain do, the author claims to have demonstrated that the localized damage in cranial cerebral injuries is traceable to skull distortion

*Holbourn, A. H. S. Mechanics of head injuries. *Lancet* 2:438-441 1943.

Distant damage, on the other hand, occurs in regions where the brain is locally fixed in relation to the skull. Adjacent cerebral tissue is thus permitted to rotate around such fixed points and to set up shear strains, which eventuate in the pathologic changes recognized as concussion, contusion and laceration. Extradural hemorrhages are said to be caused by skull distortion, whereas subdural and subarachnoid hemorrhages result either from this same cause or from shearing damage to appropriate blood vessels.

To produce shear strains, therefore, the skull and its contents must not only be struck but must also be rotated. Because of its shape the liability of compression without rotation of the skull and its contents following a blow is extremely small. On the theoretical concept that concussion with its unconsciousness is caused by separation of constituent particles to a minimal degree, in contradistinction to a laceration, when such separation is maximal, the author predicts, "The theory of head injury can be developed on the assumption that during and immediately after the blow, all factors other than the purely physical can be neglected." This includes so-called "contracoup damage." If further investigations support his demonstration, then, as he says, "One can be reasonably confident that only minor modification to the theory will be necessary to explain quantitatively the usual type of accident" — at least until another worker presents a new concept and a different explanation.

A NEW TEST FOR ACUTE BACTERIAL INFECTION

THREE chemical constituents of pneumococci are well known: the type-specific polysaccharides, the species-specific protein and a nonspecific carbohydrate. The last is apparently common to many bacteria, and recent work has shown that a protein substance reacting with this nonspecific carbohydrate is present in human serum during the acute phase of many bacterial infections but is not found after recovery, nor is it present in the serum of normal individuals. Skin tests with the type-specific polysaccharide have had a limited use, especially before the introduction of chemotherapy, both as an aid in prognosis and as a guide to therapy with antipneumococcus serum. Satisfactory preparations of both the specific and nonspecific carbohydrates

are difficult to make, and skin reactions with these substances, as with other materials, have many drawbacks.

Löfström* in a monograph just published in Sweden describes in detail a nonspecific reaction that involves the capsular swelling of pneumococci of certain types in human serum. The Type 27 pneumococcus has proved to be most satisfactory for this purpose. The reaction is carried out in exactly the same manner as the Neufeld test for the typing of pneumococci. In the latter test the pneumococcus in question shows swelling of the capsule when it is mixed with antipneumococcus rabbit serum of the homologous type. Löfström's reaction takes place with the Type 27 pneumococcus (and to only slightly less extent with Types 16 and 28) and human serums from a large variety of conditions. The author has worked out many of the physical and chemical characteristics of the serum responsible for this reaction and has applied it to the study of serums from a variety of conditions.

A number of important practical applications of this nonspecific reaction are claimed by the author. It does not occur in the serum of normal individuals but is present only during the febrile stage of bacterial infections and in some other febrile conditions associated with tissue breakdown. It cannot be demonstrated in the virus diseases that he has studied. Thus the reaction is negative with serums from patients with common colds or influenza, but becomes positive if bacterial complications intervene. The reaction occurs during acute bacterial infections of the respiratory tract, such as tonsillitis, sinusitis and pneumonia, but promptly disappears from the serum after the acute infection subsides. It is therefore offered as an aid in prognosticating the occurrence of bacterial complications of virus infections or other conditions. In cases of meningitis in which cultures are negative the test may be used to differentiate bacterial from virus infections — it is positive in all the acute bacterial meningitides, weakly positive in tuberculous meningitis and negative in lymphocytic choriomeningitis and the virus encephalitides.

The author also claims that this reaction can be used to differentiate cases of coronary occlusion

*Löfström, C.
Logic and clinical
Preliminary studies
Lofström's studies
1932, 1933.

from congestive failure without occlusion, since it is present only during the phase of coronary occlusion when tissue breakdown is taking place. Likewise he believes that the reaction may differentiate chronic endocarditis with valvular defects and subacute bacterial endocarditis, the capsular swelling being demonstrated in the latter but not in the former.

As a routine method for the clinic, the test for nonspecific capsular swelling has the great advantage that it is simple to perform and easy to evaluate. Should the author's claims be substantiated, the reaction may prove to be an extremely useful tool.

MEDICAL EPONYM

RIEDEL'S STRUMA

Professor Bernhard Moritz Karl Ludwig Riedel (1846-1916), of Jena, discussed the topic "Die chronische, zur Bildung eisenharter Tumoren führende Entzündung der Schilddrüse [Chronic Inflammation of the Thyroid Gland Leading to the Formation of Iron-hard Tumors]" at the twenty-fifth congress of the Deutsche Gesellschaft für Chirurgie, on May 30, 1896. His remarks are published in *Verhandlungen der deutschen Gesellschaft für Chirurgie* (1:101-105, 1896). A portion of the translation follows:

I present for your consideration a new, unusual property of the thyroid gland. . . .

There came under my care a forty-two-year-old man who for six months had noticed an increase in size of his thyroid gland, together with moderately severe dyspnea. There was a bilateral tumor, not very large, but extraordinarily hard and immovable. I supposed it to be a malignant goiter, and on November 30, 1883, attempted operation, exposed the tumor and saw at once that it was very firmly adherent to the carotid artery and the internal jugular vein on either side, resected a portion of the internal jugular, then after removal of a bit of the goiter about as large as a walnut, cut short the operation, since I was forced to consider the case inoperable. . . . Half a year later the man reported that he was entirely well and able to work. In the meantime we had studied the specimen and found in it no trace of any new-growth. It was an inflammatory process; infiltration with round cells was demonstrated; carcinoma and sarcoma were ruled out, and the patient had neither tuberculosis nor syphilis. . . .

Twelve years later a second case was encountered.

Inspection of the preparation gives no hint of the hardness of the growth; one would expect firm, fibrous tissue as a constituent of the tumor, but we see only masses of round cells, as described.

The growth seems even harder before operation: this is explained by the abundant firm adhesions of the tumor to the surrounding soft parts, especially with the blood vessels, nerves and trachea. . . .

It would seem . . . as though for the present only partial excision of the growth exerts an influence on the inflammatory process.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

EXECUTIVE COMMITTEE OF THE COUNCIL

On December 29, 1943, the Executive Committee of the Council, on the recommendation of the Committee on Membership and representatives from the supervising censors, took the following action:

Accepted the resignations of the following named fellows, under the provisions of Chapter I, Section 7, of the by-laws, these resignations to be effective as of January 1, 1944:

Medinger, Fred G. (nonresident), 326 South 19th Street, Philadelphia.

Strong, Seth L. (Plymouth), Marshfield Hills.

Reinstated the following named fellow, who had resigned from the Society while in good standing, under the provisions of Chapter I, Section 10, of the by-laws:

Houghton, Henry L. (Suffolk), 176 Commonwealth Avenue, Boston.

Allowed the following named fellow to change his membership from one district society to another, without change of legal residence, under the provisions of Chapter III, Section 3, of the by-laws:

Simmons, Fred A., 264 Beacon Street, Boston (Norfolk to Suffolk).

Remitted the dues, including those of 1941, 1942 and 1943, of the following named fellow who is ill and incapacitated, under the provisions of Chapter I, Section 6, of the by-laws:

Jones, Raymond C. (Worcester North), Ashby.

Reinstated following named fellows, under the provisions of Chapter I, Section 10, of the by-laws, who had been deprived of membership for the non-payment of dues, provided their arrears in dues at the time they were dropped plus the dues for 1944 be paid to the treasurer of the Society:

Karl'sberg, Isador J. (Middlesex South), 164 Main Street, Hudson. Joined 1932. Deprived 1939.

Parris, Roland O. (Barnstable), 18 Locust Street, Falmouth. Joined 1916. Deprived 1934.

Rifkin, A. (Plymouth), 197 Main Street, Brockton. Joined 1929. Deprived 1938.

The personnel of the Committee on Membership is as follows: Harlan F. Newton, *chairman*; John E. Fish; Peirce H. Leavitt; A. William Reggio; and Sumner H. Remick. The representatives of the supervising censors are as follows: William H. Allen; H. Quimby Gallupe; and Albert E. Parkhurst.

MICHAEL A. TIGHE, M.D., *Secretary*
Executive Committee

SECRETARY'S OFFICE

I believe that the following letter, recently received from Dr. Victor Johnson, secretary of the Council on Medical Education and Hospitals of the

American Medical Association, will be of interest to the members of the Society.

MICHAEL A. TIGHE, *Secretary*

December 23, 1943

Dr. Michael A. Tighe, Secretary
Massachusetts Medical Society
3 The Fenway
Boston, Massachusetts

Dear Doctor Tighe:

In the November 25 issue of the *New England Journal of Medicine* there appears, on pages 832, 833 and 834, a discussion of the relationships of the Society with the College of Medicine of Middlesex University. The letter from Dr. Stephen Rushmore is quoted in which the following statement is made:

There has been expressed a fear that hospitals approved by the Council on Medical Education of the American Medical Association would lose their status as approved hospitals if they were to accept students from more than one medical school.

It occurs to me that you might be interested in knowing the exact policy adopted by the Council on Medical Education and Hospitals of the American Medical Association with regard to students from schools not on its approved list being accepted by approved hospitals for clinical instruction. The policy of the Council is embodied in the following statement:

The interest of the Council on Medical Education and Hospitals of the American Medical Association in hospitals approved for the training of interns and residents is primarily in the maintenance of a satisfactory educational program for the training of house officers. In the case of hospitals which in addition to internships and residencies also offer training to undergraduate medical students, the Council is also

interested in instances where the hospital contemplates acceptance of students from more than one medical school.

Yours sincerely,

[Signed] Victor Johnson

VICTOR JOHNSON, M.D., *Secretary*

DEATHS

FLANAGAN — James E. Flanagan, M.D., of West Roxbury, has been reported missing as a result of the sinking of the destroyer *Turner*.

Dr. Flanagan received his degree from Tufts College Medical School in 1938. He had been practicing medicine about four years when he entered the Navy a year ago. He held the rank of lieutenant at the time of his death. He was a member of the Massachusetts Medical Society and the American Medical Association.

KERRIGAN — John J. Kerrigan, M.D., of Fall River, died January 6. He was in his sixty-sixth year.

Dr. Kerrigan received his degree from the College of Physicians and Surgeons, Baltimore, in 1906, and did post-graduate work abroad. For many years he was on the staff of the Massachusetts Eye and Ear Infirmary. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son and a daughter survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

NEW LAW REGARDING PROPHYLACTIC TREATMENT OF EYES OF INFANTS

Attention is directed to amended Chapter 111, Section 109A, of the General Laws, which requires physicians to record on the birth certificate the

prophylactic treatment of the eyes of the newly delivered child. This amendment became effective on June 2, 1943. Prior to that date the law required only that the physician or hospital officer treat the eyes of the newborn within two hours after birth with a department-approved prophylactic. The present law reads as follows:

The physician, or hospital medical officer registered under section nine of chapter one hundred and twelve, if any, personally attending the birth of a child shall treat his eyes within two hours after birth with a prophylactic remedy furnished or approved by the department, and he shall record on the birth certificate the use of such prophylactic. Whoever violates this section shall be punished by a fine of not more than one hundred dollars.

It is suggested that physicians use the left margin of the certificate to record the prophylactic used.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR DECEMBER, 1943

DISEASES	RESUME		
	DECEMBER 1943	DECEMBER 1942	SEVEN YEAR MEDIAN
Anterior poliomyelitis	15	2	1
Chicken pox	1616	1444	1511
Diphtheria	40	12	18
Dog bite	431	505	561
Dysentery bacillary	10	6	16
German measles	118	190	63
Gonorrhea	477	286	335
Measles	1319	1871	1083
Meningitis meningococcal	65	27	7
Meningitis other forms	16	10	7
Meningitis undetermined	4	0	0
Mumps	671	1080	597
Pneumonia lobar	576	327	407
Salmonella infections	4	7	4
Scarlet fever	978	1307	733

Typhoid fever	3	4	3
Undulant fever	1	2	1
Whooping cough	343	1171	828

*Pfeiffer bacillus meningitis only other form reportable previous to 1941

COMMENTS

Anterior poliomyelitis has shown the usual seasonal decline since the peak of 121 cases in September, but nonetheless the December level was fifteen times the seven year median. Diphtheria on the other hand, has been showing a steady rise since September, reaching a point nearly two and a half times the seven year median. The December prevalence has not been as high since 1935. The number of cases of lobar pneumonia was also high compared to that reported in December in recent years.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Boston, 1, Fall River, 1, Haverhill, 2, Lynn, 1, Newton, 2, North Adams, 1, Norwood, 1, Peabody, 1, South Hadley, 1, Waltham, 3, Winchester, 1, total, 15.

Anthrax was reported from Salem, 1, total, 1. Diphtheria was reported from Amesbury, 1, Barre, 1, Bedford, 1, Boston, 16, Cambridge, 1, Hopedale, 1, Medford, 1, Melrose, 1, New Bedford, 1, Salem, 1, Saugus, 1, Somerville, 11, Taunton, 6, Watertown, 1, total, 44.

Dysentery, bacillary, was reported from Adams, 1, Boston, 5, Cambridge, 1, Haverhill, 4, Lowell, 1, Worcester, 18, total, 30.

Encephalitis, infectious, was reported from East Longmeadow, 1, Holyoke, 1, Lowell, 1, Springfield, 1, Worcester, 1, total, 5.

Malars was reported from Fort Devens, 8, Haverhill, 1, Worcester, 2, total, 11.

Meningitis meningococcal, was reported from Barstable, 1, Boston, 25, Bourne, 1, Cambridge, 2, Camp Edwards, 4, Canton, 1, Chelsea Naval Hospital, 1, Cohasset, 1, Danvers, 1, Dedham, 1, Everett, 2, Fairhaven, 1, Fall River, 1, Fort Devens, 2, Framingham, 1, Gloucester, 1, Greenfield, 1; Hingham, 1, Holyoke, 1, Lawrence, 1, Lowell, 1, Milton, 1;

New Bedford, 1; North Adams, 1; Plymouth, 2; Salem, 2; Springfield, 3; Westwood, 1; Weymouth, 1; Winthrop, 1; Worcester, 1; total, 65.

Meningitis, Pfeiffer-bacillus, was reported from: Boston, 1; Lynn, 1; Springfield, 2; total, 4.

Meningitis, pneumococcal, was reported from: Fall River, 1; Marblehead, 1; Medford, 1; Oxford, 1; Worcester, 1; total, 5.

Meningitis, staphylococcal, was reported from: Fall River, 1; total, 1.

Meningitis, streptococcal, was reported from: Marlboro, 1; Springfield, 1; total, 2.

Meningitis, other forms, was reported from: Boston, 3; Methuen, 1; total, 4.

Meningitis, undetermined, was reported from: Arlington, 1; Fort Devens, 1; Springfield, 1; Worcester, 1; total, 4.

Salmonella infections were reported from: Andover, 1; Boston, 1; Haverhill, 1; Northfield, 1; total, 4.

Septic sore throat was reported from: Amesbury, 1; Boston, 13; Cambridge, 1; Lawrence, 2; Medford, 1; Milton, 1; total, 19.

Tetanus was reported from: Fall River, 1; Raynham, 1; total, 2.

Trachoma was reported from: Medway, 1; total, 1.

Typhoid fever was reported from: Boston, 1; Medford, 1; total, 2.

Undulant fever was reported from: Adams, 1; Great Barrington, 1; Hatfield, 1; total, 3.

CORRESPONDENCE

WAGNER-MURRAY-DINGELL BILL

To the Editor: It did not seem to me quite fair that the letter under date of December 2, 1943, signed by the president and secretary of the Massachusetts Medical Society should have been sent to our representatives in Congress, because as I read the letter it implies that the Society has already expressed an opinion on the subject matter involved. This I am informed is not the case.

I know an appreciable number of members of the Society who do not believe in the sentiments expressed in this letter, and therefore, irrespective of what the Council will decide in February, it seems to me only fair to inform the members from Massachusetts in Congress that a minority at least of the Massachusetts Medical Society have a different point of view. I am, therefore, sending to the Massachusetts representatives in Congress a letter, a copy of which I am enclosing.

I have always hoped that the *Journal* would be willing to present both sides of a controversial matter, so I hope that you will be willing to publish this letter with the enclosure.

CHANNING FROTHINGHAM, M.D.

1153 Centre Street

Jamaica Plain, Massachusetts

* * *

Dear Sir:

January 12, 1944

In the December 2, 1943, issue of the *New England Journal of Medicine*, on page 884, there appears a letter signed by the President and Secretary of the Massachusetts Medical Society which was sent to Massachusetts members of the Senate and the House of Representatives in Congress. This letter gives the impression that the statements expressed therein are the sentiments of the Massachusetts Medical Society. Up to the present time neither the Society nor its Council, which often expresses opinions for the Society, has taken any formal action on the merits of the Wagner-Murray-Dingell Bill. What the action of the Council of the Massachusetts Medical Society or the Society itself will eventually be in regard to the Wagner-Murray-Dingell Bill remains for the future to decide. In the meantime I would like to call your attention to the fact that there are many members of the Massachusetts Medical Society who are not in sympathy with the statements expressed in this letter of December 2, 1943, referred to above and who believe that there is a possibility to accomplish a tremendous improvement in the delivery of medical care to the citizens of Massachusetts by developing a program along the general lines outlined in the Wagner-Murray-Dingell Bill.

A group of doctors with whom I am connected has made a careful study of the medical aspects of Senate Bill 1161 and has offered constructive criticism in regard to the Bill. I am enclosing a copy of the statement of this group thinking that it might be of interest to you.

Sincerely yours,

CHANNING FROTHINGHAM, M.D.

President of the Massachusetts Medical Society (1937-1939)

BOOK REVIEWS

Doctors Aweigh: The story of the United States Navy Medical Corps in action. By Rear Admiral Charles M. Oman (MC) U. S. N. 8°, cloth, 231 pp., with 10 illustrations. Garden City, New York: Doubleday, Doran and Company, Incorporated, 1943. \$2.50.

The subtitle gives the key to this clear-cut, well-written story of forty years' experience in the United States Navy. The author has seen plenty of action, and he knows how to report it. Here is the story of the preparedness and efficiency of the Navy Medical Corps at Pearl Harbor on that peaceful sunny morning of December 7, 1941, which will thrill and please any doctor. Again one may read of the astounding adventures of Dr. Wassell and of Dr. White on the *Lexington* and the story of the brilliant appendectomy performed by Pharmacist's Mate Lipes while the submarine to which he was attached rested on the bottom of the Pacific. These and many other tales, along with good advice, make sound reading and leave one proud and grateful for the high standards of the United States Navy and the splendid men who maintain them.

Pictorial Handbook of Fracture Treatment. By Edward J. Compere, M.D., and Sam W. Banks, M.D. 8°, cloth, 35 pp., with 171 illustrations. Chicago: The Year Book Publishers, Incorporated, 1943. \$4.25.

Recent advances in the management of fractures have resulted in the introduction of so many new methods that the general practitioner, who in most cases must be the one to institute the first treatment to which a fracture victim is subjected, should be acquainted with those procedures that have been shown to have been attended with the most gratifying results.

This small volume of Compere and Banks presents in compact and well-illustrated text a discussion of the essentials for diagnosis and treatment. The basic facts concerning repair in bone, — based on knowledge of the pathology of fractures, — the rate of healing, and causes of delayed union, together with a clear presentation of methods of reduction, the principles of aftercare and the complications that sometimes follow, are included in the first part of the book. The four remaining sections are devoted to the upper and lower extremities, the trunk, the face and the skull. Dislocations are also included. Many line drawings and photographs of x-ray films are used to illustrate the various types of fracture and their reduction and fixation by measures that have proved satisfactory.

Both the authors and publishers have acquitted themselves most creditably, and the practicing physicians have at their service a most helpful guide to their efforts.

Diseases and Injuries of the Larynx: A textbook for student and practitioners. By Chevalier Jackson, M.D., Sc.D., LL.D. and Chevalier L. Jackson, M.D., M. Sc. Second edition 8°, cloth, 633 pp., with 197 illustrations. New York: The Macmillan Company, 1942. \$8.00.

This is a new edition of a textbook that has become a classic in the short time since the appearance of the original edition in 1937. Surgeons within and outside the specialty are by now familiar with it, and many general practitioners have found it to be their best adviser in borderline cases. The style is most vivid and personal, and when reading the book, one is subject to the sensation of being present at one of the widely known courses of the authors.

There are 11 color plates, more than 100 halftones and 22 pen and pencil drawings to clarify the clinical picture. The new chapter on war surgery is an important and timely addition. Incidence, etiology, special pathology and accessory injuries in war are discussed, together with their peculiar symptoms and the treatment and prognosis; next, the authors consider organization for care of the wounded, chemical warfare by asphyxiating, irritating and poisonous gases and smoke and, finally, the psychical laryngeal traumas of war.

In its new form, the textbook will without doubt continue to speak *viva voce* to any member of the profession who turns to it with his medical or surgical problems regarding the larynx.

PATHOLOGY, CLINICAL MANIFESTATIONS AND TREATMENT OF LESIONS OF THE INTERVERTEBRAL DISKS*

ALBERT OPPENHEIMER, M.D.†

LACONIA, NEW HAMPSHIRE

LESIONS of the intervertebral disks are extremely common, but do not induce clinical manifestations in every case. If present, clinical signs and symptoms are sometimes almost indistinguishable from those caused by diseases of the viscera, joints, muscles and other parts. In many cases, therefore, it is difficult to decide whether the symptoms should be attributed to a disk lesion or to some other cause. Accordingly there is a divergence of opinion about the clinical significance and appropriate treatment of these lesions. Some surgeons ascribe many and different symptoms to certain lesions of the disk; others tend to discount the same lesions as incidental abnormalities. Such a discrepancy seems to demand a reinvestigation of the problem by means of statistical methods.

On the basis of 826 cases of disk lesions observed during the last eight years, of a control series of 200 persons without symptoms, and of another control series of 100 persons with complaints suggestive of disk lesions, an attempt has been made to ascertain whether correlations can be established between the clinical and the anatomical findings, and whether principles can be defined by which treatment may be directed.

PATHOLOGY

The common disk lesions seem to fall into two main groups, those caused by rupture and those due to degeneration. As a result of trauma or strain, a piece of cartilage may be detached from a normal disk,¹ or the nucleus pulposus may be squeezed out of the disk center.^{2,3} The displaced material may be pressed beyond the disk margin, either through the fibers of the longitudinal ligaments—for example, backwards into the spinal canal, where it may encroach on the cord^{4,5}—or vertically, into an

adjacent vertebral body, through congenital defects⁶ or traumatic fissures⁷ of the osseous and cartilaginous surfaces. It appears that forward and backward displacement occurs when the disk is less resistant than the bone, and that intrusion of disk material into the vertebrae implies that the bone is less resistant than the disk; but the two modes of displacement may combine.

With advancing years many disks normally lose in turgor and volume and grow flat and inelastic as a result of dehydration and increase of fibers of the disk cartilage.⁸ These morphologic alterations are probably signs of a change of the colloidal phase of the connective tissue. They are believed to be caused by the innumerable unnoticed injuries of daily life.⁷ In some persons this wear and tear seems to cause a premature aging or degeneration, especially of those disks that are located in the most movable vertebral regions—that is, the lower cervical and lower lumbar segments.^{9,10}

In addition to this quasi-spontaneous degeneration, fibrosis and flattening may develop as a result of disk rupture and of diseases of vertebral bone. Rupture of the disk, both into the vertebral body and through the longitudinal ligaments, often sets up a reaction marked by increasing fibrosis of the disk cartilage, indistinguishable histologically from involutionary degeneration.^{3,6} Bone disease may involve the disks either directly or indirectly. Infection of the vertebral body may spread directly into them through the sievelike lamina cribrosa; although resistant against most infections,³ a disk, once infected, deteriorates rapidly,¹¹ and residual disk cartilage may undergo degeneration. But even when it escapes infection, a disk adjacent to an infected vertebral body usually grows thin and fibrous in the course of several months or years (Fig. 1), although the bone infection itself may have become arrested in the meantime. Since the disk, which is normally avascular during adult life,⁶ receives its nutrition from the vertebral body,⁷ it is conceivable that degeneration occurs in these cases because nu-

trition was inadequate or faulty during the period of bone infection.

It should be recalled at this point that nothing in the pathology of the disk differs from the pathology of cartilage in general. The nucleus pulposus, the

FIGURE 1. Flattening of the Intervertebral Disk as a Result of Infection of a Vertebral Body.

The arrows point to small areas of rarefaction in the fourth lumbar vertebral body. The superjacent intervertebral space is about half the width of the normal subjacent interspace, owing to flattening of the disk. The patient, a forty-two-year-old man, developed sudden pain in the back during recovery from a blood-stream infection due to *Staphylococcus aureus*.

presence of which somewhat complicates the picture, is an inert part that, although derived from primitive connective tissue, has no more life of its own than, for instance, the synovial fluid; it plays no active part in determining the morbid processes observed. Cartilage is a connective tissue which the omnipotent mesenchymal cell fails to regenerate effectively. It may either undergo necrosis in its various forms and phases or be invaded and replaced by vascular connective tissue. Although small scattered areas of newly formed cartilage may be produced, this repair is hardly ever sufficient to restore the original volume and resiliency of injured cartilage. Lesions of the disk exemplify this rule. The injured parts of a disk grow flat, less elastic and more fibrous, no matter what were the cause and nature of the

original injury.³ As the disk thins down, the vertebrae at this level approach each other. As a result the following changes may take place.

Marginal osteophytes (hypertrophic spondylitis). As the bufferlike action of the disk diminishes, the horizontal vertebral surfaces sustain increased static stress and the edges of the vertebral bodies may come into contact during certain movements. This slight but continual trauma may cause minute fractures,⁶ which normally¹² heal with callus formations. The fractures recur, and the callus formations grow, especially into the free space between the vertebral margin and the longitudinal ligaments,¹³ thereby forming the marginal overgrowths (Fig. 2) that resemble exostoses of peripheral joints and are therefore commonly designated as osteoarthritis of the spine. According to its definition, however, osteoarthritis is a disease of the synovial joints and is marked by the wearing off of free articular cartilages. The joint formed by the disk and vertebrae has no free cartilages; it is not a synovial joint but a synchondrosis, which has been named the "vertebral symphysis."¹⁴ Hence marginal osteophytes at the level of flattened disks do not fit the anatomical definition of arthritis; and since it has been shown that they are not associated with the clinical symptoms of arthritis,¹⁴ these osteophytes should not be grouped with arthritis.

Osteoarthritis of the apophyseal joints (hypertrophic spondylarthritis). At the level of a thinned disk the articular processes are crowded together, and their articular surfaces, or facets, become displaced, usually with the superjacent facet sliding backward and downward along the subjacent facet (Fig. 3).^{15, 16} This often causes straining of the surrounding capsules of the apophyseal joints and the ligaments and may produce a gradual wearing off of the articular cartilages that are affixed to the facets¹² — a lesion that corresponds in every respect to osteoarthritis of the peripheral joints and is a true arthritis of the spine. As in osteoarthritis of the peripheral joints, eburnation, ecchondroses and exostoses may, but need not, develop along the articular surfaces involved. This hypertrophic spondylarthritis occurs in less than 20 per cent of all cases of disk thinning; in the majority of cases the cartilages of the apophyseal joints seem to resist the strain successfully.¹²

Bony impingement. The displacement of articular processes may amount to impingement of the tip of the subjacent facet on the base of the superjacent facet.¹⁵⁻¹⁷ The impinging tip may produce in the opposing base an erosion resembling a drill hole, with subsequent reactive eburnation of the surrounding bone. This was noted in 2.8 per cent of this series.

Contact between spinous processes. When the disk thins down, contiguous spinous processes may come into contact and form eburnation and osteophytes like the margins of the vertebral bodies.¹⁸ This was recorded in 0.6 per cent of this series.

FIGURE 2 Secondary Osteophytic Changes in the Vertebral Bone and Joints as a Result of Disk Thinning

The fourth lumbar intervertebral space is less than half the width of the other interspaces, owing to flattening of its disk (x). Osteophytes have formed at the central margins of the vertebral bodies (black arrows), but the apophyseal joints have remained normal (white arrows). On the tracing the stippled areas correspond to the secondary lesions. The patient, a forty-one-year-old woman, complained of sciatic pain; there was no backache.

FIGURE 3 Secondary Spondylarthritis Changes in the Vertebral Bone and Joints as a Result of Disk Thinning.

The fourth lumbar intervertebral disk is flattened (x). The facets at this level are ragged and eburnated, and the intervening apophyseal joint space is narrowed (white arrows). This is a diskogenetic spondylarthritis. On the tracing the stippled areas correspond to the secondary lesions. The patient, a forty-seven-year-old man, complained of severe pain in the lower back; the movements of the lumbar spine were severely restricted.

Narrowing of the neural foramen. At the level of a thinned disk the neural foramen grows narrow.^{13, 17, 19-20} The nerve root that passes through it may become compressed.¹⁶ Marginal osteophytes

arising from the posterior margins of the vertebral bodies²² and from the tips of the articular processes,¹⁷ as well as ossification of the yellow and intra-articular ligaments¹⁷ and swelling of the apophyseal-

joint capsule,¹² may add to the compression. The most frequent sites of pressure on nerve roots are the lower cervical and lower lumbar segments, not only because disk thinning is commonest in these regions,^{9, 10} but chiefly because the nerve roots are thicker and the foramina not proportionally wider than in other vertebral sections. Since the caliber of the nerve root, the original width of the foramen and the amount of narrowing vary from case to case,^{14, 23} compression of nerve roots does not occur in every case of disk thinning. Narrowing of neural foramina was present in 92 per cent of the cases of disk thinning in this series.

Bulging of disks into the spinal canal. A softened, fibrosed or thinned disk may, under the pressure of superincumbent parts, be flattened out so that it protrudes beyond the vertebral edges. Since the longitudinal ligaments at the level of a flattened disk grow loose,¹³ they yield and bulge sideward, together with the disk. The protruding parts may cause pressure on the spinal cord.²⁴

The secondary changes above enumerated have been designated as "diskogenetic," in order to imply that they are all caused by the disk lesion. One may speak of diskogenetic osteophytes, diskogenetic spondylarthritis and so forth, in order to distinguish these lesions from similar alterations that are due to some other cause. Marginal osteophytes, for instance, may be present at the level of perfectly normal disks, especially as a result of low-grade bone infection, and osteoarthritis of the apophyseal joints may be produced by several different factors.^{12, 14} The clinical manifestations associated with disk lesions have been named "the diskogenetic syndrome," and the totality of anatomical and clinical findings has been termed "diskogenetic disease."¹⁰

CLINICAL MANIFESTATIONS

Not every disk lesion produces clinical manifestations. In a series of 200 apparently healthy persons not conscious of any symptoms, flattened disks were found in 22 cases (11 per cent). Conversely, in a series of 312 unselected cases of disk thinning, clinical signs and symptoms pointing to a lesion of the involved vertebral segments were present, or had been present at different periods, in 267 cases (85 per cent). These figures dovetail with a sufficient degree of accuracy, but are not necessarily representative. In many cases the symptoms are transient or recurrent rather than persistent; and when a patient happens to be free of pain and discomfort at the time of the x-ray examination, he is classified with the "silent" group, although he may develop symptoms in the future, or may have forgotten about symptoms that he had in the past. One often hears patients state that they never had any pain or disability until they are reminded by a companion of the "sciatica," "rheumatism" or "sore shoulder," for which they consulted physicians and osteopaths in previous years.¹²

The main difficulty in evaluating the clinical significance of disk lesions consists in the fact that signs and symptoms virtually identical with those caused by diseases of the disk may be the result of involvement of viscera, muscles, bursas, peripheral joints, spinal cord, and peripheral nerves. In a series of 100 patients complaining of symptoms suggestive of lesions of the cervical disks, flattening of the disks was demonstrable in 89 cases (89 per cent); in 34 of these, 11 showed evidence of bursitis, 5 of acromioclavicular arthritis, 2 of tuberculosis of the shoulder, and 17 of aortic sclerosis, coronary disease and cardiac failure. In the remaining 11 cases, myalgia, polyneuritis and subdeltoid bursitis were present in the absence of disk lesions in 8 patients, and the source of the complaint could not be ascertained in 3 cases. This shows that clinical manifestations suggestive of disk lesions are due to some other diseases in about 10 per cent of the cases, and that their connection with a demonstrable disk lesion is questionable in at least another third.

From these observations it should be inferred that the roentgenographic demonstration of a diseased disk does not prove the diskogenetic origin of the complaint. This limitation was perhaps not sufficiently emphasized in early reports, including mine.^{17, 25} On the other hand, the figures indicate that in about two thirds of the cases, certain clinical manifestations are in all probability due to the disk lesions disclosed on roentgenograms.

Axiomatic notions have obscured the problem. For instance, some authors^{23, 24, 26} maintain that narrowing of a neural foramen cannot amount to compression of the nerve root by the surrounding bone. Anatomic specimens showing such a compression were presented by Hadley¹⁶ in 1938. In the same year, unquestionable clinical evidence of damage to nerve roots passing through narrowed neural foramina was submitted.²³ The signs and symptoms noted in these patients were found to reappear in those cases in which examination suggested, but did not prove beyond doubt that the clinical manifestations were actually caused by the disk lesions present. These manifestations were as follows:

Pain in the back or neck at the level of the involved disk. This is not common; it was noted in 21 per cent of this series; its incidence varied with the vertebral region involved.

Limitation of vertebral movements at the level of the involved disks. This was recorded in 18 per cent of the series and varied with the localization of the disk lesion.

Manifestations of radicular neuralgia or neuritis. These are multifarious, consisting of pain in the peripheral region that corresponds to the involved nerve segment, weakness and atrophy of muscles, hyperesthesia, paresthesia and anesthesia, and trophic changes of the skin

muscle and bones. Manifestations of radicular neuralgia and neuritis were present in 72 per cent of the series.

CORRELATIONS BETWEEN CLINICAL AND ANATOMICAL FINDINGS

A study of the correlations between the clinical and anatomical findings above classified seems to show that the clinical manifestations of disk lesions vary with a number of factors.

Vertebral region involved. Flattening of cervical disk was associated with pain in the neck in 4 per cent of the cases; with limited motion of the cervical spine in 11 per cent; and with recurrent pain in the shoulders, forearm, precordium and fingers in 72 per cent. In the presence of flattened thoracic disks pain in the back was noted in 29 per cent of the patients; limited motion of the thoracic spine could not be determined, since the movements of this region are normally very scant; and persistent or recurrent intercostal neuralgia, occasionally accompanied by recurrent herpes zoster, was present in 36 per cent of the cases. Of the patients with flattened lumbar and lumbosacral disks, 37 per cent complained of pain in the low back, 31 per cent of limited motion in this region, and 49 per cent of recurrent sciatic pain.

Thinning of disks. The incidence and severity of the clinical manifestations were not proportional to the degree of disk thinning, as measured by the width of the intervertebral space. No correlation could be established between any of the clinical signs and symptoms, on the one hand, and the degree of disk thinning, on the other.

Involvement of other vertebral parts. The presence, amount and size of osteophytes at the anterior margins of the vertebral bodies did not seem to determine the incidence, kind and severity of the clinical manifestations. All things being equal, the signs and symptoms were the same in patients with and those without osteophytes. Osteophytes at the posterior margins of the vertebral bodies seemed to accentuate and maintain radicular nerve pain; all things being equal, the incidence of radicular neuralgia was 43 per cent higher in the presence than in the absence of these exostoses.

Bony impingement of articular processes was associated with persistent backache and with limitation of vertebral motion in all the cases; no case of bony impingement without definite clinical symptoms was encountered. Radicular pain was present in 69 per cent of these patients. In 89 per cent of the patients with diskogenetic involvement of the apophyseal joints (hypertrophic spondylarthritis), pain and diminished mobility of the involved vertebral region were noted, often associated with tenderness on pressure (Fig. 4). Conversely, only 8 per cent of all patients with thinned disks but without involvement of the apophyseal joints were

conscious of pain, discomfort or stiffness of the involved parts of the spine (Fig. 5). Contact between spinous processes did not seem to alter or accentuate the symptoms present and was noted in an equal number of patients who were free of symptoms. The cases of bulging of a degenerated disk into the spinal canal were not numerous enough to warrant statistical evaluation.

These observations indicate that the clinical manifestations of disk lesions are determined, at least to some extent, by two main factors: the vertebral region involved, and the condition of the apophyseal joints. Lesions of cervical disks rarely cause any symptoms in the neck itself, but lesions of the lumbar and lumbosacral disks cause low-back pain and limitations of movements in about one third of the cases. On the other hand, lesions of cervical disks induce radicular manifestations in a majority of cases, and lesions of the lumbar and lumbosacral disks cause radicular neuralgia in only about one half of the cases. Lesions of the thoracic disks seem to remain clinically silent in about two thirds of the patients. Pain and limited motion in the spine seem to develop chiefly when the apophyseal joints have become involved, irrespective of the seat of the lesion.

On the negative side stand two findings that, although conspicuous, do not seem to play a part in determining the clinical manifestations in most cases. These are osteophytes of the vertebral margins—so-called "osteo-arthritis of the spine"—and the amount of disk thinning. Marginal osteophytes, no matter how large and numerous, do not cause symptoms unless they arise at the posterior vertebral edges and project into the neural foramina. These posterior osteophytes occur not infrequently in the cervical spine,^{13, 17, 22, 23} but are rare in the lumbar region and usually absent in the thoracic vertebrae; they are difficult to recognize on routine radiograms and are usually overlooked. The only influence that osteophytes of the anterior vertebral edges seem to have, according to my observations, is that they may limit anterior flexion of the spine when they are bulky; but the patients are rarely conscious of this limitation, even when it can be definitely shown on roentgenograms made during movements of the spine. Finally, the amount of disk thinning did not seem to be responsible for the incidence and severity of clinical manifestations in this series. In many patients who were free of symptoms complete obliteration of the intervertebral spaces was present, whereas in others severe radicular neuralgia seemed to be caused by only moderate thinning of disks.

These observations confirm the contention previously made—namely, that lesions of the disks cause symptoms felt in the periphery rather than in the spine, and that, in the presence of disease of the spine, pain and rigidity of vertebral regions are caused in most cases by involvement of the apophys-

eal joints. Since disk lesions induce arthritis of the apophyseal joints in only about one fifth of the cases, symptoms felt in the spine are not common,

said to resemble toothache in the shoulder, wrist or gluteal region or in sciatic distribution is the commonest complaint for which medical advice is

FIGURE 4. Result of Disk Thinning with Involvement of Apophyseal Joints.

The fourth lumbar interspace is narrowed, and the apophyseal joint at this level has ragged facets and a narrowed articular space (arrow, right lower corner). Compare with normal superjacent apophyseal joint. The patient, a thirty-six-year-old woman, had severe persistent pain in the back, with tenderness on pressure (x, left upper corner), impaired forward flexion (right upper corner) and no sciatic pain.

and the vertebral origin of peripheral pain easily escapes recognition.

CLINICAL COURSE OF DISKOGENETIC DISEASE

On the basis of the data above reported, and taking into account the experience with other patients not included in this series, one may draw a composite picture of the usual course of diskogenetic disease.

Early stage. Rarely before the age of thirty, and usually after the age of forty-five, recurrent pain

sought by these patients. The pain tends to be severer in the early morning, when it may awake the patients, and subsides in the course of the day to reappear in the evening. There is rarely pain in the back or neck at this stage, but a sensation of moderate stiffness may be present; it is often compared by patients to the muscle soreness that follows unwonted exercise. The symptoms may subside gradually without treatment in the course of about two years and need not recur. A history of a trauma incurred many years previously, such as a fall from

a horse, a diving accident and so forth, is obtained in many cases

Moderately advanced stage The pain in the extremities, shoulder and gluteal region becomes more pronounced, and the intervals of relative or complete relief grow shorter. The movements of the painful shoulder or leg are definitely limited apparently as a result of muscular defense. Sensory disturbances, such as numbness and tingling of the fingertips and of the soles, set in, and so-called 'electric' sensations in the arm or leg may wake the patients

the floor are some of the movements that cannot be carried out. Trophic changes, such as herpes zoster (Fig 6), may occur. Atrophy of the skin, especially in the region proximal to the nails, may develop, and the phalangeal bones may become rarefied.³ In many cases the reaction of degeneration is positive. Finally a peculiar resilient swelling of the wrist, fingers or foot may develop, and the involved limb becomes completely disabled (Fig 7). At this stage, spontaneous improvement does not occur, and the hand or foot becomes crippled if not treated

FIGURE 5 Result of Disk Thinning, with Involvement of Apophyseal Joints

The fourth lumbar interspace is narrowed (arrows, left upper corner) but the apophyseal joints at this level are normal (white arrows, right upper corner). This patient had severe sciatica with trophic edema of the right foot (arrow, right lower corner) with perfect mobility of the lumbar spine.

with a sudden shock at night. The grip of the hand may become weak, and the involved leg feels heavy. Usually some degree of atrophy of the deltoid, biceps, interosseous and thenar muscles, or of the corresponding muscles of the leg, is noted. Spontaneous recovery at this stage seems to be exceptional.

Advanced stage As the disease progresses, the pain becomes persistent and muscular atrophy becomes definite. Pain in the low back and neck may be superadded. The movements of the involved limb are definitely limited owing to weakness of the muscles. Carving meat, fastening a dress on the back, tipping the hat and lifting an object from

Secondary deviations of the bones produce an appearance suggesting a severe deforming arthritis, but the joints are not involved and passive mobility is preserved. From these manifestations the symptoms of rupture of the disk into the spinal canal differ in the acute onset and persistence, but not in kind and severity. Such signs as back pain induced by sneezing and coughing are certainly not typical of disk rupture and may be observed in the presence of various other lesions of the vertebrae.

CONTRIBUTING FACTORS

In this series there were as many men as women patients with symptoms referable to disk lesions.

The highest incidence of diskogenetic symptoms in women was found in the age group of sixty to seventy years, but in men in the fifty-to-sixty-year group. Weight, height and general build did not seem to play significant parts. There were short, tall, stocky and slender people with the same symptoms, but symptoms seemed to appear at a younger age in stocky than in slender patients. Occupational and social factors could not be ascertained as contributing causes.

In 74 per cent of the patients, the diskogenetic symptoms were preceded by an infection, such as sore throat, sinusitis or cystopyelitis, and the com-

to the infection becomes manifest as a result of infection, and that infection precipitates the appearance of clinical symptoms. The influence of mental factors is difficult to determine.

TREATMENT

Reasonably complete follow-up records are available in 322 cases. The patients treated were observed during periods varying between eight months and seven years. Most of them were examined at intervals of eight to ten months.

An injured disk cannot be repaired; the fibrous tissue produced cannot be reversed into cartilage.

FIGURE 6. *Persistent Herpes Zoster as a Result of Diskogenetic Narrowing of Neural Foramens with Radicular Neuritis.*

The neural foramen between the eleventh and twelfth thoracic vertebrae is narrowed, and arthritic deformities encroach upon it (black arrows, right lower corner). There was a herpes zoster in the corresponding skin areas, persisting for a period of seven years. The pictures of the lower row were taken twenty-one months after those of the upper row. The patient was a sixty-three-year-old man.

plaint persisted after the infection had subsided. One may speculate whether this can be explained on the basis of a disturbed vitamin B metabolism. It is known that in the presence of most infections the vitamin B reserve is diminished, especially in the liver. It is conceivable that this deficiency affects first or foremost those nerve segments that have already sustained some damage as a result of compression in narrowed neural foramens. If infection alone were responsible for neuralgia in these cases, one would expect other nerve segments also to become involved. One may perhaps say that a localized nerve injury that was clinically silent previous

Most of the clinical manifestations, however, are caused not by the disk lesion itself but by the secondary alterations in the neural foramens and apophyseal joints resulting from the constriction of the intervertebral space. Rupture of the disk into the spinal canal is not always an exception to this rule; as will be shown, some of the symptoms associated with disk rupture may be caused by the associated disk thinning. If the narrowed intervertebral space could be widened permanently, no other treatment would perhaps be necessary, but this has not yet been achieved. Spinal fusion and grafting does not help to hold the vertebrae permanently a

normal distance, since in the course of a few years the fused or grafted osseous parts yield to the stress exerted by superincumbent parts. Treatment, therefore, still remains confined to attempts at controlling and eliminating pressure on the cord, radicular neuritis and manifestations of spondylarthritis. Although from the academic point of view this does not appear to be satisfactory, it often brings about considerable relief from, and sometimes complete disappearance of, pain and disability in this group of patients.

The surgical treatment of rupture of the disk into the spinal canal has been exhaustively discussed in the literature.^{5, 9, 27, 28} The scientific achievement

intervertebral space grew progressively narrow in the course of three or four years in spite of spinal fusion, probably because the ruptured disk degenerated and became flat, as set forth above. The recurrence of symptoms was probably produced by compression of nerve roots within the foramens.

In spite of these observations, the definite value of surgery should not be minimized, but perhaps sufficient time has not yet elapsed to judge on the long-range results of this operation.

Conservative treatment^{29, 31} consists in attempts at preventing further damage to the disks, in eliminating contributing factors and in control of pain.

FIGURE 7. Atrophy and Deformity of the Right Hand as a Result of Diskogenetic Radicular Neuritis. The disks below the fourth and sixth cervical vertebral bodies are flat, and the neural foramens at these levels are narrowed (arrows). The interosseous muscles of the right hand are severely atrophic, and the fingers are claw-like. Mobility of neck was perfect. The patient, a fifty-eight-year-old man had had recurrent pain in the right shoulder for about six years. One year became swollen and very painful. The swelling subsided, but he had any pain or stiffness of the neck. The case illustrates the manifestations.

and practical value of this procedure are untested, but there seems to be no complete agreement on the indications for operation. On the one hand, the fact that a patient consults a doctor because of persistent backache and sciatic pain has been considered a sufficiently valid reason for operation, on the other hand, it has been repeatedly shown that numerous lesions may produce the same clinical manifestations and roentgenographic appearance as does a ruptured disk.²⁹

Of 10 patients operated on by leading surgeons five years ago and earlier, 4 are still free of symptoms, but the clinical manifestations recurred in 6 patients, of whom 2 are now almost completely incapacitated. The failures in this series were due to two main causes. In 2 cases the symptoms were not caused by the rupture alone, but in part by the associated compression of nerve roots in the neural foramens and the displacement of the facets. Although compression of the cord was relieved by the operation, pressure on the roots in the foramens seemed to persist. In the 4 other cases the involved

Jarring of the spine can be prevented to some extent by wearing rubber heels and soles, refraining from lifting heavy objects and bending at the hip and knee joints instead of stooping when reaching for an object on the floor. Infections should be brought under control, and suspected dietary deficiencies should be corrected. In some cases control of pain can be achieved by these measures alone; in others the occasional use of analgesics is required, and in a third group it is necessary to teach the patients how to avoid assuming a lordotic position. During rest, the legs should be bent at the hip and knee joints, and a thick hard pillow should be placed under the neck, in order to prevent the cervical and lumbar regions from assuming a lordotic position at night. Lordosis increases an existing constriction of the neural foramens,³⁰ as well as an associated displacement of the articular processes. Gentle active and passive bending, recommended as a limbering-up exercise during the morning, often helps patients to overcome the pain and discomfort experienced especially at this time of the day.

The use of back braces is rarely beneficial, probably because most of these appliances hold the spine in a position of lordosis. In fact, several of the patients in this series experienced material relief as soon as these braces were removed. Various modes of traction, used in the past and recommended by various authors, including myself, have not proved to be satisfactory in recent years and have been discontinued by me and my associates.

In 582 cases roentgen-ray therapy was used for the control of backache and of radicular nerve pain. The value of this mode of treatment is not generally recognized, and many authors believe that its effects are highly questionable. It is true that almost nothing is known about the mechanisms that underlie the results of small doses of radiation. Moreover, the application demands experience and requires the kind of personal supervision that the overburdened radiologist can ill afford to give. The doses and intervals have to be adapted to the case, the phase of the disease and sundry other factors. Hence the treatment cannot be standardized. In institutions where the pressure of more important work makes this personal supervision unfeasible, the results have been generally disappointing. Radiologists who are in the fortunate position to devote some time to this method find the results are worth the effort.

Using a technic previously reported,¹⁴ it was found that in 74 per cent of the patients the therapeutic effects were due to the radiation itself, but not to the associated psychologic factors. Permanent relief from pain and discomfort was obtained in 21 per cent of the cases, temporary relief in 55 per cent, and doubtful or negative results in the remaining 24 per cent. In patients in whom only temporary relief was achieved, repetition of roentgen-ray therapy proved to be effective in controlling recurrences. Treatment was given with 140 to 160 kilovolts, and 5 to 20 milliamperes, with 0.5 mm. copper and 1.0 mm. aluminum filtration, through portals 15 cm. square, the single doses measured on the skin being between 35 and 75r according to the duration of symptoms, with total skin doses of between 200 and 700r per series.

Among the patients who did not respond to the various measures above summarized, the majority had well-marked arthritic changes in the apophyseal joints at or above the level of the involved disks; some others presented bony impingement of the corresponding articular processes. In the latter group, subsequent treatment with body casts, traction and eventual spinal fusion did not prove to be satisfactory.

The best results of roentgen-ray therapy were noted in patients with trophic disturbances of the skin, muscles and bones in the peripheral segments corresponding to the involved disk. With striking uniformity these severe lesions disappeared within a number of weeks after the institution of roentgen-ray irradiation, and the disabled limbs resumed

normal function soon afterward. There seems to be no other mode of treatment by which these lesions can be arrested.

CONCLUSIONS AND SUMMARY

Disk lesions are about twice as common as is duodenal ulcer. This high incidence may be explained by the evolutionary development of the human spine. The vertebral column of man does not differ essentially from that of many quadrupeds; it is closely similar to that of the cow.³² This means that a system of bones and joints that was originally adapted to bear almost no vertical stress sustains in man the whole impact of the upright posture and locomotion. In some persons the vertebral bone is less resistant to strain than are the disks, but in a majority of adults the disk cartilages are the weakest parts of the spine. Wear and tear cause numerous minimal injuries from which the disk rarely recovers completely, since its cartilage cannot be effectively regenerated. Cartilage undergoes degeneration, with increase of fibrous tissue. The result is loss of turgor and volume of the disk. The same changes may be caused by a single severe injury and by certain diseases of the adjacent vertebral bodies from which the disk receives its nutrition. Disk rupture is one of the injuries which may be followed by degeneration. No matter what is the cause of the injury and degeneration, flattening of disks leads to narrowing of the corresponding intervertebral spaces, associated with displacement of articular processes, narrowing of the neural foramen and abnormal contact between vertebral bodies.

The clinical manifestations depend on these secondary alterations rather than on the degree of disk thinning. Narrowing of the neural foramen may cause radicular neuritis if the corresponding nerve root is compressed, but compression does not occur in every case because of the variable relations between the caliber of the nerve and the degree of constriction. Pain in the back and limitation of vertebral movements are less frequent and seem to be caused predominantly by diskogenetic involvement of the apophyseal joints.

The conspicuous predominance of symptoms experienced in radicular distribution in the periphery over symptoms felt in the spine itself is perhaps due to the fact that the disk, being devoid of nerves,³³ does not hurt when diseased. The most sensitive parts in its neighborhood are the nerve roots and the apophyseal joints. Arthritis of these joints develops in about 20 per cent of the cases of disk lesions and produces pain in the back with limitation of vertebral motion. In the majority of cases, however, the apophyseal joints remain intact, and symptoms of nerve-root compression develop without pain and rigidity of the spinal region involved. This means that in most cases lesions of disks cause symptoms felt in the limbs without symptoms felt in the back or neck.

The signs and symptoms of radicular neuralgia and neuritis are often indistinguishable from those of myalgia, peripheral arthritis, bursitis and pain referred from diseased viscera. Moreover, in the age group in which the incidence of disk lesions is highest, involvement of joints, bursas and viscera is also common. The difficulties encountered in recognizing disk lesions are chiefly caused by these diagnostic limitations. When disk lesions coexist with other diseases that are known to induce peripheral pain, the differential diagnosis can be made only after exhaustive clinical studies are made.

Treatment may be surgical or conservative. Surgical removal of a ruptured disk followed by spinal fusion does not always prevent symptoms caused by subsequent disk thinning from developing after several years. Conservative treatment yields satisfactory results in about 75 per cent of the cases.

PARENTERALLY ADMINISTERED AMINO ACIDS AS A SOURCE OF PROTEIN IN MAN*

S. H. BASSETT, M.D.,† R. R. WOODS, M.D.,‡ F. W. SHULL, A.B.,§ AND S. C. MADDEN, M.D.¶

ROCHESTER, NEW YORK

RECENT experiments have shown that the ten amino acids believed to be essential for the growth of rats¹ and for the formation of plasma proteins in dogs² are capable on intravenous or subcutaneous administration of replacing all or nearly all the dietary protein required by man for nitrogen equilibrium or retention and that the parenteral administration of these amino acids, supplemented with glycine, is very well tolerated by man, as it is by the dog. Aside from their fundamental interest, these observations appear to point to a valuable means of restoring body protein or protecting against its depletion in the diseased or injured person. Protein depletion is a serious complication that because of its insidious development frequently goes unrecognized until it reaches an advanced state. Among the hazards to which it predisposes may be mentioned lowered resistance to infection,^{3, 4} lowered resistance to intoxication⁵⁻⁷ and impaired healing of wounds.⁸⁻¹⁰ In many forms of illness or injury the dietary intake of protein is reduced or at best normal, whereas the need for it is usually increased.^{11, 12} Reduced appetite or impaired capacity for ingesting, retaining or absorbing protein may be responsible for the inadequate intake of protein.

Search for solutions acceptable to the body and capable of providing the nitrogen requirements on parenteral administration has been pursued of late and reviewed recently, and a fairly comprehensive bibliography has been compiled.¹³ The readiness with which the dog utilizes solutions of pure amino acids such as those listed in Table 1 contrasts with its lower tolerance for all other protein digests,^{2, 14-16} and prompted the clinical observations now in progress. The entire investigation will be reported later, but the initial observations are of sufficient interest to be recorded now. There follows the report of the case that formed the basis of this experiment.

CASE REPORT

The patient was a 63-year-old farmer who had developed a gastrojejunocolic fistula. Twenty-three years previously a gastroenterostomy had been performed for relief of pyloric obstruction and a perforating pyloric ulcer. He remained free from gastrointestinal complaints until a year previously, when he began to have diarrhea and lost weight. The fistula was discovered by x-ray and a colostomy was done proximal to it. Most of the lost weight was regained, but after ten months the fistula was still open. Operation was performed

for excision of the fistula and closure of an apparently non-functioning gastroenterostomy. The colostomy remained patent. Subsequently the patient did poorly. Abdominal discomfort, nausea and vomiting were associated with an inadequate intake of food and a marked decline in weight. After 4 weeks had elapsed, the colostomy was closed successfully, and because of the poor nutritional state and the possibility that parenteral feeding would be beneficial, the patient was transferred to the Metabolic Unit.

A careful and complete record of the respective weight or volume of the food or fluid received was kept throughout the investigation. All urine, feces, vomitus and gastric washings were saved and analyzed for total nitrogen by the macro-Kjeldahl procedure. The urine was also analyzed for its content of urea and ammonia nitrogen, by the method of Van Slyke and Kugel.¹⁷ The nitrogen content of the food was calculated from data published in standard tables of reference (Rose) and in a few instances from data furnished by the commercial processor of the food. The weight was obtained at frequent intervals and under as nearly uniform conditions as possible.

The composition of the amino acid mixtures is given in Table 1. Each mixture was stirred into distilled water just

below the boiling point. Filtration through hard paper was followed by autoclaving for 15 minutes at 15 pounds' pressure. The final volume of the solutions varied from 1250 to 1550 cc. and the reaction was approximately pH 5. The solutions were water clear and had a faint yellowish tinge after autoclaving.

Administration of the amino acid solutions was simple and rapid. The day's quota was divided into two equal injections, except for the first two days of Period 2 (Table 2), when the 50 per cent larger intake was given in three equal injections. Usually the morning dose was given subcutaneously, and the afternoon dose intravenously. Intravenous injections (50 gm.) were given on the average within 60 minutes and as rapidly as within 40 minutes (3.8 mg. of nitrogen per minute per kilogram of body weight). Subcutaneous injections were given on the average within 130 minutes and as rapidly as within 70 minutes (2.2 mg. of nitrogen per minute per kilogram of body weight).

Tolerance for the amino acid solutions was high. Its limits were not reached during this experiment, although the rates of injection used were more rapid than any recorded for protein-digest solutions with freedom from clinical disturbance. No rise in body temperature as a result of the injection was observed. In fact, during periods 5 to 10 (Table 2), the temperature did not rise above 98.6°F. On two occasions thrombosis of a forearm vein followed injections, more apparently as a result of inept venipuncture than of irritation from the solution. The lower pH of the solutions as compared with that of blood appeared to afford no intolerance. The plasma chlorides and the carbon dioxide combining power of the blood remained normal throughout the period of ob-

servation with suitable administration of sodium and chloride. Similar high tolerance for these solutions has been found in dogs.¹⁶ In these animals the upper limits of tolerance without clinical disturbance are not reached by injections as rapid as 10 mg. of nitrogen per minute per kilogram of body weight, at which rate an adequate daily protein requirement is given within 15 minutes.¹⁶

The first 20 days (Periods 1 to 4) were characterized by severe pyloric obstruction, and the amount of food that

adequate amount of nitrogen and number of calories listed in Table 2. At least 107 gm of nitrogen was lost during this period.

The patient was returned to the Surgical Service at the end of Period 4 because further radiologic studies suggested increasing pyloric obstruction and the possibility of a penetrating peptic ulcer. Nine days following the close of the period, a subtotal gastrectomy was performed with excision of a penetrating pyloric ulcer. After several transfusions and a

*Nitrogen of feces and vomitus although not tabulated included

†Exclusive of amino acids

‡Nitrogen received from two transfusions not included

passed into the duodenum was small. Although the nitrogen intake of the first 5 days (Period 1) was adequate, on account of the amino acid injections (Mixture Vh), the calories from other sources were minimal and the loss of nitrogen amounted to about 3 gm daily. During Periods 2 and 3 the patient continued to receive injections of amino acids (Mixture Vh and Mixtures Vh and Vn, respectively) and the caloric intake was increased by the daily intravenous infusion of 2000 cc of 10 per cent glucose. This, together with small oral feedings of carbohydrate and fat, brought the daily caloric intake from all sources to an average of about 1500 calories. Nitrogen equilibrium was achieved in both periods. In Period 4, parenteral feedings were discontinued, with the result that the patient was able to eat and retain only the in-

adequate dietary regime the metabolic study was resumed on the 10th postoperative day (Period 5). A good positive diet containing about

Mixture Vn was resumed chiefly of carbohydrate and fat. More than 80 per cent of the nitrogen intake was from amino acids, and there was a satisfactory retention of nitrogen. The loss of weight noted in Periods 5 and 6, when nitrogen was being retained, appears to have been associated with discontinuance of the vigorous postoperative infusion of saline solutions, and suggests that this form of therapy may have been the cause of subclinical edema.

In Periods 7 and 8, Mixture Vx was given, and the caloric intake was increased. More nitrogen was retained, and there was a gain of 2.3 kilograms in weight. During the succeeding 10 days (Periods 9 and 10), the intake of nitrogen was entirely from food. Both the positive nitrogen balance and the gain in weight were somewhat greater.

A follow-up report from the patient 3 weeks later indicated continued improvement in general health and a continued rapid gain in weight.

COMMENT

When sufficient calories are provided, the nitrogen obtained from the amino acid mixtures is well utilized. It should not be concluded that the nitrogen obtained from natural foods is better utilized, for the following reasons. First, the amino acid mixtures used may not be the optimal ones. Second, more than 20 per cent of the nitrogen contained in them is present in those certain unnatural isomers that are said not to be utilizable by rats for purposes of growth.¹ Third, the patient was obviously in better condition at the end of Period 8, than at the end of Period 6, when the second course of amino acid solutions was begun, and it may be argued that his metabolic machinery was functioning more efficiently at the end of Period 8, thus giving a certain advantage to Periods 9 and 10, during which the natural food protein was tested.

There was no significant change in the concentration of plasma protein during the metabolic study. It averaged 5 gm. per 100 cc. during Periods 1 to 3 and rose to 5.6 gm. during Periods 6 to 8.

Of the urinary nitrogen, the amount not excreted as urea and ammonia was higher during the periods of amino acid injection than it was during the period of comparable nitrogen intake from food protein. This increase has been recorded in dogs receiving amino acids or protein digest parenterally.^{2, 14, 15} Its nature will be the subject of further investigation. It is apparently a function of the route of administration and not of the type of the nitrogen being administered, for it is not present in dogs when the same protein digest or amino acid mixture is given by mouth.

The glycine was originally added with the hope that it might furnish amino nitrogen for the in vivo synthesis of other nonessential amino acids. There is evidence from experiments in dogs that this hope is largely unrealized, but that the presence of glycine somewhat improved tolerance to the parenteral administration of the amino acid solutions.¹⁶

This report demonstrates the value in medical treatment of a synthetic mixture of pure amino acids given parenterally, but does not prove that this mix-

ture contains all the amino acids required by man. At all times, as indicated in Table 2, nitrogen of unknown amino acid composition was being consumed. It is equally true that the oral diets used by other workers testing the amino acid requirements of human beings contain 5 to 10 per cent nitrogen of unknown composition.^{18, 19} In another patient, to be reported soon, amino acid solution similar to Mixture Vx provided a positive nitrogen balance for a five-day period when it was the only source of exogenous nitrogen.

SUMMARY

A case is reported in which solutions of the amino acids essential for the growth of rats were given intravenously and subcutaneously without any clinical disturbance, and with satisfaction of the requirements of nitrogen equilibrium and formation of body protein. This fact is physiologically interesting and possibly of some practical importance in the treatment of patients.

MEDICAL PROGRESS

SYPHILIS

G. MARSHALL CRAWFORD, M.D.*

BOSTON

PUBLIC-HEALTH ASPECTS

SOME extremely encouraging developments regarding the public-health aspect of syphilis, and particularly the sociologic facet, have been reported in publications during the last year. The Massachusetts law governing premarital examinations has not been in operation for sufficient time to allow a statistical survey of its usefulness. Talbot¹ has recently reported on the Connecticut law, with highly satisfactory findings. During the first seven years of its operation, 750 men and 690 women were found to have positive serologic tests for syphilis; this is equivalent to 14.1 per 1000 marriages. About 50 per cent of the patients diagnosed as having syphilis were unaware of their infection. Since the Connecticut law went into effect in 1936, the incidence of congenital syphilis has progressively decreased. The marriage rate dropped the first year, but since then it has increased steadily; in 1942 it was more than twice the 1932 figure. It may be said that the Connecticut law has been effective as a case-finding procedure and a measure for reducing the incidence of congenital syphilis. Physicians should have a greater incentive for taking routine serologic tests for syphilis. The education of the general public in regard to this disease should also be well served.

A consultation program on a statewide basis has been operating satisfactorily in New York. Kroll² reports on the operation of the plan, and it sounds quite workable. The state was divided into districts with a full-time consultant in each area. Local physicians were approached in two ways. Letters were sent out to all those in active practice; one of every eight made a response and the consultant visited their offices. The second approach was a visit to all physicians who had reported cases of syphilis under treatment, whether or not advice had been requested; one of every three of this group accepted assistance. Consultation may be obtained by mail or through a visit to the local physician's office with discussion of the case. An examination of the patient was carried out wherever possible, and such diagnostic procedures as dark-field examination, lumbar puncture and so forth were performed when requested. The problems of the participating physicians concerned late latent syphilis, the choice of drugs or the management of neurosyphilis in 50 per cent of the cases. The next 40 per cent of questions concerned the following in the order given: early syphilis, congenital infections, serologic interpre-

tations, infectiousness, syphilis in pregnancy and cardiovascular syphilis. This program has apparently stimulated greater interest among general practitioners and served to educate them in more capable practice. The result has been greater co-operation with the public-health authorities. In addition to the consultation program, diagnostic clinics are operated in large centers.

From the purely sociologic standpoint and aside from other laudable aspects, California has taken two worth-while steps. A venereal-psychiatric clinic has been opened in San Francisco.³ The purpose of this service is to provide re-education and readjustment for girls and women who have histories of promiscuous sex relations and who may spread or who are spreading venereal disease among the civilian population and armed forces. The socioeconomic background of these patients is studied, and every attempt is made to remedy their maladjustment. Emphasis is placed on rehabilitation and relocation of the patients through the co-operation of local agencies. A special court, the Separate Women's Court, has also been opened in San Francisco to meet the problem of sexually promiscuous women who are arrested.⁴ Every effort is made to provide means for adequate referral for first offenders who present a potentiality for re-education and readjustment. The medical co-ordinator of the Separate Women's Court is the chief of the Division of Venereal Diseases. These measures seem most rational.

A new approach to the source-finding and suppression of venereal disease has been suggested by Williams.⁵ His so-called "facilitation process" has been pursued in Vancouver, British Columbia, with considerable success. This approach to the control of venereal disease lies in the premise that the acquisition of a venereal disease is dependent on two factors: namely, the source of the infected person and the circumstances whereby the source is made accessible to the healthy person. Action dealing with the source has been a common procedure in all control campaigns. Action directed toward the "facilitators" to remove conditions rendering the source accessible is the key to Williams's plan. The facilitation process comprises those community conditions associated with the direct or indirect, witting or unwitting participants, usually for monetary gain of the third person, whereby persons suffering from common venereal disease are made accessible for intimate exposure to healthy persons. The facilitators or third-person participants, are madams, pimps and procurers with whom may be associated unethical

*Instructor in dermatology, Harvard Medical School, assistant dermatologist, Massachusetts General Hospital.

physicians, lawyers, finance companies and real-estate agencies. Managers and owners of premises may also be in the ranks of the facilitators. The attitude of certain civic administrators, health departments and law-enforcement agencies may place the officials of these administrations, and also the public, in the position of being facilitators. Those engaged in the commerce of liquor are last, but by no means least. Dance halls, taverns, rooming houses and employees of these establishments, as well as taxicab-drivers, hotel clerks, bellhops and so forth, may be of great importance. Serious attention to such components of the facilitation process, as well as closing disorderly houses, has led to remarkable results in British Columbia. The Canadian Navy's monthly incidence of venereal disease on the West Coast has been only about half that on the East Coast. Canadian Army and Air Force statistics show a better record in the British Columbia district than in any other military area. These satisfactory figures substantiate Williams's claim for success in his campaign. He believes that "energy expended in the suppression of facilitation in a community is far more profitable from the public-health standpoint than the usual misdirected efforts at 'suppression of prostitution' which harassed the exploited, sick prostitute and left untouched the wealthy, healthy facilitator." This seems to be one of the most worthwhile campaigns for the control of venereal disease on record.

The widespread effect of the campaign of the United States Public Health Service to control venereal disease is reflected in innumerable articles. Practically every medical journal carries one or more publications in this vein from time to time, and there is considerable overlapping in their content. Attention can profitably be called, however, to police activities as outlined by Ness.⁶ A National Advisory Police Committee appointed by Federal Security Administrator Paul V. McNutt unanimously endorsed an eight-point agreement as a national standard for law-enforcement officers throughout the United States. This agreement was drawn up jointly by the War Department, the Navy Department and the Federal Security Agency as the official federal policy for the control of venereal disease. Point 6 of the agreement recognizes prostitution as the chief source of venereal disease. In those communities that have clamped down on prostitution, there has been no crime wave or increase in rape cases. On the contrary, this action has frequently resulted in corresponding improvements in the criminal situation. The National Advisory Police Committee has recognized that the repression of prostitution is not the only method of control to protect the health and welfare of the armed forces, war workers and girls engaged in prostitution. An intelligent over-all war-protection program is necessary. Such a program must provide measures for the social and economic rehabilitation of the girls

arrested, as well as the fundamental measures for attacking conditions which breed prostitution.

SYPHILIS IN THE ARMED FORCES

Encouraging figures on the incidence of venereal disease have been published by Weber.⁷ During World War I the rate was 86.7 per 1000. During 1941 the rate for the Army was 42 per 1000, and in the first six months of 1942 it had dropped to 38 per 1000. This is most heartening in view of the expected increase that has always accompanied the forays of Mars. Vonderlehr and Usilton⁸ have published an analysis of serologic reports of near 2,000,000 men of draft age up to the end of August 1941. This is the young adult male group, in whom the incidence of syphilis would be expected to be higher than that in any other. The rate of prevalence of syphilis, based on positive and doubtful blood tests among the selectees examined, was found to be 45.3 per 1000. The figures for white selectees in this group was only 17.4 per 1000. Most encouraging is the reduction in the incidence of venereal disease in the Navy.⁹ The rate for all venereal disease was 80 per 1000 in 1940, 51 per 1000 in 1941 and about 36 per 1000 in 1942. The trend is thus downward by 50 per cent over the three-year period, and the Navy venereal-control officers can be justly proud of this result.

The British have apparently been having more trouble than have we, according to published figures. The increase in venereal disease since the beginning of the present war has been serious enough to command special attention. The British public has been more reticent about publicity in regard to venereal disease than has the American public, and only recently have newspaper and magazine articles on this subject been printed. The Ministry of Health has issued a new defense regulation (No. 33B), under which it will be possible in certain cases to compel persons infected with venereal disease to undergo medical treatment.¹⁰ Taking the number of civil infections in syphilis alone, the most trustworthy test of the wartime increase, there were 5000 in 1939, 5600 in 1940 and 7300 in 1941. If to this are added the infections among British military services, the total increase in syphilitic infections amounts to 100 per cent. Venereal disease in Scotland showed an even greater increase, the incidence there having more than doubled since the outbreak of the war. In Australia there had likewise been an increase in the incidence of early syphilis¹¹; until fairly recently all soldiers in the Home forces having syphilis were discharged from the army as medically unfit and instructed to report to their own physicians or local boards of health for treatment. Re-enlistment was possible after a satisfactory course of treatment. Australian Army personnel having syphilis are now discharged.¹² By a recent arrangement, infected soldiers are treated at special hospitals until no longer infectious, and are then transferred to a compa-

for duty while their weekly injections are continued. In addition, an educational campaign is under way in the Australian Army.

SYPHILIS IN INDUSTRY

The man hours lost by workers in war industry as a result of venereal infections have reached serious enough proportions to warrant more active attempts to control syphilis in their field. Schwartz and Markel¹⁴ have approached the problem from the standpoint of protecting the employee as well as the employer. The syphilitic worker, even in the primary or secondary stage of the disease, is a negligible source of infection to employees of the same sex. Neurosyphilitic patients should not be employed where lapses of consciousness, such as the dropping of explosives, may result in accidents. Workers having syphilis in the tertiary stage should not be employed where they are exposed to the action of nitrates and other nitrogenous compounds that have a marked effect on the vascular system or to lead and carbon disulfide, which affect the central nervous system. Even workers who have had adequate treatment for tertiary syphilis should not be exposed to the action of such compounds. Many occupational diseases can simulate syphilis in its various stages, and these are well portrayed in Schwartz and Markel's paper. This is a profitable publication for thorough study by all physicians engaging in industrial practice.

The Surgeon General of the United States Public Health Service has appointed an advisory committee to assemble current authoritative information and to formulate basic principles applicable to a program of venereal-disease control in industry. This committee has outlined the objective of such a program in regard to medical and public-health aspects and employees' problems, as well as those of the employer. Anderson et al.¹⁵ elaborate on these objectives and outline the manner in which the plan can be operated. It is emphasized as of the utmost importance that the results of medical examination be considered confidential as between the worker and the medical staff. Venereal-disease forms should be filed in the medical department for the use of the medical staff only, and not in an open file. Employees found to have syphilis should be referred to a reputable source for medical attention and not discharged so long as the industrial physician is notified at regular intervals regarding continuation of treatment. The plant physician making a tentative diagnosis of syphilis or gonorrhea should without delay acquaint the appropriate health authority with the facts of the case. It is properly emphasized that there is no reason for denying employment to an applicant or for discharging an employee because a medical report has given evidence of syphilis or gonorrhea, provided the worker co-operates satisfactorily in the treatment program. Nelson¹⁶ has written on the same problem in cogent fashion. One

point well emphasized is that there is no relation whatever between the blood test and the infectiousness of syphilis. Nelson further states that it is to the best interests of both industry and society to put the infected person to work or to keep him at his job contingent on such treatment as may be necessary. This is safer than to dismiss him with completely unsupervised treatment or none at all. Nelson states that the use of the blood test as a key to employment in general, for the purpose of excluding those who may be dangerous in certain occupations, is as ridiculous from the point of view of public safety, and as unsound medically, as it is unjust. In many industries the problem is already being intelligently handled. How soon it is to be solved in others will largely depend on whether the well-informed physician or the uninformed layman is to determine the medical policy.

An example of a well operated plan was published by Yeager.¹⁷ Since 1934 the Remington Arms Company has been giving complete physical examinations to all employees, including a blood serologic test for syphilis. Applicants in a communicable or a contagious stage of syphilis cannot be employed, in conformance with the Connecticut state law. New employees in the noninfectious stage can be hired provided they take adequate treatment, a plant physician keeping check on this. Provision can be made for treatment at clinics for applicants who are unable to pay, and the employee's disease is kept strictly confidential. Applicants or employees in a communicable stage are considered for employment after they have been rendered noninfectious by treatment. Although the Selective Service statistics show that Connecticut has the lowest percentage of syphilis in any state, the incidence among the employees of the Remington Company's Bridgeport works is even lower. The employees are most grateful to the company for making it possible to diagnose the condition, particularly those who had no previous knowledge of their infection or thought they were cured.

The control of venereal disease in industry will save time and money for all concerned, as pointed out by Anderson.¹⁸ It will also achieve a higher standard of efficiency and increase the industrial worker's earning capacity and life expectancy. The syphilitic blind cost society about \$10,000,000 a year, and paretic patients in state institutions cost another \$6,500,000. Congress appropriated \$12,500,000 for the control of venereal disease in 1943, and the states will raise some \$7,000,000. To each of these sums industry will contribute liberally through taxes. From the cost angle alone, therefore, industry has a considerable stake in venereal-disease control. The state health departments may have to provide mobile facilities for the employees in the smaller plants that have no regular medical service. One such department has a blood-test trailer operating among small plants and communities.

It should be pointed out that the safest worker regarding the spread of syphilis is one with a positive serologic test for syphilis who is under treatment, after passing the infectious stage; he or she is also immune to reinfection. If venereal-disease control can be furthered by education of industrial workers, and industry itself can be shown the fallacy of discharging workers on the basis of a positive serologic test alone, a great step will have been taken. Strikes in war plants arouse the indignation of the public because of wasted time and money and loss of production. Venereal disease can be responsible for these same losses.

EXPERIMENTAL RESEARCH

The vast amount of plasma in use by the armed forces and the rapid rise in the popularity of blood banks increase the importance of a study concerning the survival of *Treponema pallidum* in the various preparations. Ravitch and Chambers¹⁹ investigated this problem in regard to frozen plasma, with experiments on animals. They were able to show that human and rabbit plasma heavily inoculated with *Tr. pallidum* and frozen at -20°C . for forty-eight hours or longer is not infectious for normal rabbits.

A study of the similarities of several representative types of bismuth preparations used in the therapy of experimental syphilis has been reported by Clausen, Longley, Green and Tatum.²⁰ Five bismuth compounds in common use were employed, with both intramuscular and intravenous administration to animals. Their toxicity was studied and the therapeutic efficiency of each was computed. The similarity of the minimal curative dose, regardless of the route of administration, and the similarity in the toxicity of the various preparations when given intravenously suggested that basically all bismuth preparations ultimately act in a common form rather than in the form in which they are injected. The effect of ammonium chloride on the mobilization and excretion of bismuth in normal and syphilitic rabbits was studied by Brown, Kolmer and Rule.²¹ In the presence of massive doses of bismuth subsalicylate this effect of ammonium chloride may increase the toxic effects of the bismuth. In the treatment of acute testicular syphilis of rabbits, the increased mobilization of bismuth was without therapeutic value. In human beings, however, the opinion was expressed that this increased mobilization of bismuth may lead to an enhanced therapeutic effectiveness. It was pointed out that since acidosis increased the toxic effects of bismuth, it is not advisable to administer ammonium chloride to syphilitic persons predisposed to the acidotic state.

It would be ideal to have an arsenical preparation that could be used effectively by oral administration in the treatment of syphilis. Rosenthal²² has studied Mapharsen in this respect. Mice infected with a trypanosome were cured by oral doses. Rabbit

syphilis was then attacked in the same fashion, with satisfactory results. Glutathione and cysteine were found to decrease the toxicity of Mapharsen without effecting its therapeutic activity, and the drug was better tolerated when one of these was given. Similar work was carried out by Brown, Kolmer and Rule.²³ Working with rats, these investigators found that the trivalent arsenical drugs were far less toxic when given by oral administration than when injected intravenously. Mapharsen was least toxic by a large margin. Rabbits with acute testicular syphilis were then treated by the oral administration of trivalent arsenicals. In terms of arsenic administered, it was found that the therapeutic effectiveness of Mapharsen by oral administration is higher than in the case of arsphenamine and neoarsphenamine. The same group²⁴ then studied the toxicity and therapeutic effectiveness of arsenical preparations by intramuscular administration. Here again, Mapharsen was found to be of lower toxicity than the other drugs and of high therapeutic effectiveness. These results suggested that the intramuscular injection of Mapharsen in sterile peanut oil may prove to be of value in the treatment of human syphilis. A schedule of five daily intramuscular injections was projected for a massive arsenotherapy schedule for early syphilis. If clinical experiment should bear out this possibility, many of the dangers of massive therapy might be reduced.

There has been considerable disagreement regarding primary optic atrophy in neurosyphilis. It seems possible that visual damage in treated cases may be due to the syphilis itself, to the therapeutic agent or to a combination of factors. Longley, Clausen and Tatum²⁵ studied the experimental production of primary optic atrophy in monkeys, which were chosen since their eyes have been found to resemble those of human beings more closely than do the rabbit's. Five arsenical compounds were administered intravenously to different groups of animals in gradually increasing doses at weekly intervals. In these experiments, blindness was produced in monkeys in varying degrees by each of the drugs. The authors believe that this work provides an experimental basis for detecting the blinding potentialities of arsenical compounds for man. It also provides the means for a study of prophylactic procedure designed to reduce or eliminate optic atrophy as a sequence of chemotherapy for neurosyphilis. Tryparsamide amblyopia was studied by McDermott, Webster, Baker, Lockhart and Tompsett²⁶ from the standpoint of nutritional degeneration of the optic nerve in rats. Deficiencies of various vitamins were produced in certain groups of animals, and these with normal rats, were treated with tryparsamide. Only in the presence of adequate amounts of vitamin B complex (yeast) and vitamin A (cod-liver oil) did rats fail to develop degeneration of the optic nerve. This was found to be true whether or not they were treated with tryparsamide, although the latter in

tensified the degeneration. The implications of this work seem obvious.

PATHOLOGY

Autopsy material of the last twenty-five years at Yale University School of Medicine has been analyzed for syphilis by Rosahn and Black-Schaffer.¹⁷ Five thousand three hundred autopsies were performed during this time. Those done on persons twenty years of age or over numbered 3907, and of these 380 (9.7 per cent) had clinical, laboratory or post-mortem evidence of syphilis. In this group of 380 syphilitic patients there were 156 (41 per cent) with morphologic lesions of syphilis. Ninety (58 per cent) of these patients with anatomic lesions died primarily as a result of their syphilis. When the material was analyzed from the standpoint of sex incidence, it was found that women appeared to have a significant resistance to the tissue changes of late syphilis, and that this was independent of race. When the syphilitic and nonsyphilitic portions of this autopsy material were compared, it was found that the mere presence of syphilis significantly reduces longevity, regardless of whether or not tissue lesions result. Twenty per cent of nonsyphilitic patients survived after the age of seventy, as against only 10 per cent of those with syphilis. Life-insurance actuaries would do well to review these findings.

SYPHILIS AND CANCER

The prevalence of syphilis among a sample series of 7761 cancer cases was studied by Levin, Kress and Goldstein.²⁸ Of the 3151 male patients, 3.2 per cent were found to have been reported as syphilitic, and among 4610 female patients, 1.7 per cent had syphilis. Males with cancer of the tongue showed a greater prevalence of syphilis than did those with cancer of other sites, in the ratio of 5:1. Among females with cancer of the uterine cervix, the corresponding ratio was 3.5:1. This higher prevalence of syphilis is similar in both instances to that reported in other studies and has long been recognized.

MORPHOLOGIC DIAGNOSIS

An interesting variation in dark-field microscopy technic is suggested by Witlin.²⁹ This author recommends examining the slide under the low and high-dry objectives before applying oil to the coverslip. Time is thereby saved in locating the organism, and it can then be properly identified by observation under the oil-immersion lens. The importance of dark-field examination of lesions of the cervix is emphasized by Sharp, Alexander and Schoch.³⁰ It is stressed that although a cervical lesion may appear to be traumatic or merely an exacerbation of chronic cervicitis, a dark-field examination may reveal spirochetes. This applies particularly to the examination of contacts of known syphilitic patients and of patients with seronegative primary syphilis. The use of the dark-field in the diagnosis

of secondary syphilis has been portrayed by Agee.³¹ The employment of this technic in primary lesions of syphilis, genital or otherwise, and in moist papules is generally recognized as an essential diagnostic procedure. It is the advisability of searching for spirochetes in other types of skin lesions that Agee emphasizes. This is obviously intelligent when one considers that the presence of positive serologic tests with skin lesions suspected of being those of syphilis does not necessarily prove the case as secondary. Also, the beginning of treatment can be expedited by obtaining a positive dark-field reaction without waiting for a positive serologic report. Dry or closed secondary lesions can be abraded vigorously by means of a scalpel or dry gauze. If serum does not exude freely, it may be necessary to squeeze the area to express such material.

From time to time various stains for *T. pallidum* have been described. These procedures are useful under some circumstances where a dark-field condenser is not readily available or where the patient cannot be transported. Smears can be obtained in outlying communities and properly examined elsewhere within a comparatively short time. Perrin³² describes such a method, which in his hands has proved simple, rapid and reliable.

REINFECTION

The problem of reinfection versus superinfection versus recurrence of the infectious phase has always been a source of considerable discussion. There has been an apparent increase in reinfections since the advent of so-called "massive therapy," as will be shown below. This has brought up the advisability of reviewing the criteria of reinfection, and several papers on this subject have appeared. Schoch and Alexander³³ have expressed a somewhat altered concept of reinfection in view of their experiences, and record 10 cases. Four patients sustained reinfection following orthodox antisyphilitic therapy. Six of 103 patients were reinfected following a ten-day course of intensive arsenotherapy (1200 mg. of Mapharsen) for early syphilis. The details of these cases are reviewed, and for the most part they fit well into the category of reinfections. The authors state that whether or not the six cases of reinfection following intensive therapy are acceptable as such, they serve to emphasize the importance of developing new and more rapid epidemiologic approaches to syphilis when short-term intensive schedules of treatment are used. Schoch and Alexander offer a hypothesis to explain the fact that more reinfections seem to be occurring. This explanation intimates that patients with early syphilis treated by intensive methods are prevented by treatment from developing any immunity against reinfection, that the chemotherapeutic prophylactic effect of intravenous arsenotherapy disappears within a brief time after treatment ceases, and that such patients are prone to expose themselves so soon to the infectious

It should be pointed out that the safest worker regarding the spread of syphilis is one with a positive serologic test for syphilis who is under treatment, after passing the infectious stage; he or she is also immune to reinfection. If venereal-disease control can be furthered by education of industrial workers, and industry itself can be shown the fallacy of discharging workers on the basis of a positive serologic test alone, a great step will have been taken. Strikes in war plants arouse the indignation of the public because of wasted time and money and loss of production. Venereal disease can be responsible for these same losses.

EXPERIMENTAL RESEARCH

The vast amount of plasma in use by the armed forces and the rapid rise in the popularity of blood banks increase the importance of a study concerning the survival of *Treponema pallidum* in the various preparations. Ravitch and Chambers¹⁹ investigated this problem in regard to frozen plasma, with experiments on animals. They were able to show that human and rabbit plasma heavily inoculated with *Tr. pallidum* and frozen at -20°C . for forty-eight hours or longer is not infectious for normal rabbits.

A study of the similarities of several representative types of bismuth preparations used in the therapy of experimental syphilis has been reported by Clausen, Longley, Green and Tatum.²⁰ Five bismuth compounds in common use were employed, with both intramuscular and intravenous administration to animals. Their toxicity was studied and the therapeutic efficiency of each was computed. The similarity of the minimal curative dose, regardless of the route of administration, and the similarity in the toxicity of the various preparations when given intravenously suggested that basically all bismuth preparations ultimately act in a common form rather than in the form in which they are injected. The effect of ammonium chloride on the mobilization and excretion of bismuth in normal and syphilitic rabbits was studied by Brown, Kolmer and Rule.²¹ In the presence of massive doses of bismuth subsalicylate this effect of ammonium chloride may increase the toxic effects of the bismuth. In the treatment of acute testicular syphilis of rabbits, the increased mobilization of bismuth was without therapeutic value. In human beings, however, the opinion was expressed that this increased mobilization of bismuth may lead to an enhanced therapeutic effectiveness. It was pointed out that since acidosis increased the toxic effects of bismuth, it is not advisable to administer ammonium chloride to syphilitic persons predisposed to the acidotic state.

It would be ideal to have an arsenical preparation that could be used effectively by oral administration in the treatment of syphilis. Rosenthal²² has studied Mapharsen in this respect. Mice infected with a trypanosome were cured by oral doses. Rabbit

syphilis was then attacked in the same fashion, with satisfactory results. Glutathione and cysteine were found to decrease the toxicity of Mapharsen without effecting its therapeutic activity, and the drug was better tolerated when one of these was given. Similar work was carried out by Brown, Kolmer and Rule.²³ Working with rats, these investigators found that the trivalent arsenical drugs were far less toxic when given by oral administration than when injected intravenously. Mapharsen was least toxic by a large margin. Rabbits with acute testicular syphilis were then treated by the oral administration of trivalent arsenicals. In terms of arsenic administered, it was found that the therapeutic effectiveness of Mapharsen by oral administration is higher than in the case of arsphenamine and neoarsphenamine. The same group²⁴ then studied the toxicity and therapeutic effectiveness of arsenical preparations by intramuscular administration. Here again, Mapharsen was found to be of lower toxicity than the other drugs and of high therapeutic effectiveness. These results suggested that the intramuscular injection of Mapharsen in sterile peanut oil may prove to be of value in the treatment of human syphilis. A schedule of five daily intramuscular injections was projected for a massive arsenotherapy schedule for early syphilis. If clinical experiment should bear out this possibility, many of the dangers of massive therapy might be reduced.

There has been considerable disagreement regarding primary optic atrophy in neurosyphilis. It seems possible that visual damage in treated cases may be due to the syphilis itself, to the therapeutic agent or to a combination of factors. CASE 30041

PRESENTATION OF CASE

A forty-nine-year-old housewife entered the hospital because of jaundice of four days' duration.

The patient was in fair health until about five weeks before admission, when she began to feel tired and run down. She developed a gnawing pain in the right upper quadrant. There was some numbness of the fingertips, and stiffness of fingers in the mornings. About two weeks before admission she had a shaking chill, with fever of 102°F. associated with sore throat, headache, running nose and generalized aches and pains. Ten days prior to entry, she had a crampy pain in the right upper quadrant lasting for a few minutes. The malaise, anorexia and coryza persisted. She had a cough productive of yellowish-brown mucoid sputum. The temperature was about 101°F. Four days before admission she noted jaundice of the skin and scleras. At the same time the urine became dark yellow, and the stools a light tan. She developed a severe headache and had waves of nausea but no vomiting.

Twelve years before her present admission the patient was admitted to another hospital for functional bleeding. She received 1400 milligram-hours of radium. Ten years later she was readmitted to the same hospital for essentially the same complaint. A dilatation and curettage was of no value, and about six months later she was given 2000 milligram-hours of radium. This was followed some months later by radiation proctitis. She was then transferred to this hospital, where a hysterectomy was performed ten months before her present entry, the diagnosis being pyometrium. At that time she also had a bilateral femoral-vein ligation following thrombophlebitis of the right calf. The proctitis improved with the removal of fecal impactions, and she was discharged well, seven months before the present admission.

Physical examination showed an obese woman in no distress. There was moderate icterus of the skin and scleras. Small petechiae were peppered over the lower abdomen, left arm and lower back. The axillary and inguinal lymph nodes were small

and nontender. The heart was percussed 1 cm. to the left of the midclavicular line. The sounds were regular and of good quality. There was a soft systolic murmur, heard loudest at the apex. The lungs were clear. The abdominal wall was pendulous. The liver edge was palpable three or four fingerbreadths below the costal margin. It was firm, smooth and slightly tender. The spleen was palpable three fingerbreadths below the costal margin; it was not tender. Pelvic examination showed a bilaterally lacerated cervix covered with an atrophic mucosa. There was slight tenderness in the right vault, but no masses could be palpated.

The blood pressure was 140 systolic, 75 diastolic. The temperature was 98.6°F., the pulse 72, and the respirations 24.

Examination of the blood showed a red-cell count of 4,300,000, with 12.5 gm. of hemoglobin. The white-cell count was 4000, with 72 per cent neutrophils, 22 per cent lymphocytes and 6 per cent monocytes. The platelets were slightly diminished, the red cells showed slight variation in size and shape, with many target cells, and the neutrophils showed a shift to the left. A blood Hinton test was negative. The urine was dark amber and acid, with a specific gravity of 1.020; there was no albumin, but a ++ bile test. It was positive for urobilinogen in 1:20 dilution (normal, 1:10). The stools were light tan and guaiac negative. The bleeding time was 6 minutes, and the clotting time 15 minutes. A fragility test showed beginning hemolysis in 0.40 per cent and complete hemolysis in 0.28 per cent sodium chloride solution. A tourniquet test gave 25 petechiae per square centimeter after fifteen minutes with a pressure of 100 mm. of mercury (normal, 6 to 20). The blood sugar was 104 mg. per 100 cc. The direct van den Bergh was 6.6 mg., the indirect 9.6 mg. The total protein was 5.2 gm. per 100 cc., with 3.2 gm. of albumin and 2.0 gm. of globulin. The nonprotein nitrogen was 31 mg. per 100 cc. The prothrombin time was 27 seconds (normal, 18 seconds). The hematocrit was 46.5. A cephalin flocculation test was ++++ in twenty-four hours and ++++ in forty-eight hours. There was 100 per cent retention of bromsulfalein.

Plain films of the abdomen showed several ring shadows in the right upper quadrant that had the appearance of gallstones. A gastrointestinal series and films of the chest were negative.

The patient was given a high-carbohydrate, high-vitamin B, low-calorie and low-fat diet, supplemented daily by 500 cc. of intravenous dextrose. In the next few days the jaundice definitely increased. She had several, occasionally severe but usually moderate colicky attacks of right-sided abdominal pain. The pain was mostly in the upper quadrant and on one or two occasions radiated to the shoulder.

On the tenth hospital day she became orthopneic, with a feeling of substernal oppression, and

*On leave of absence.

forced to sit up. There was profuse sweating. This episode presumably lasted for a few minutes. The temperature was 100°F., the pulse 96, and the respirations 24. The white-cell count was 5200, with 82 per cent neutrophils. The urine had a + test for albumin and a ++ test for bile. The stools became brown and remained so. The direct van den Bergh was 12.7 mg., the indirect 17 mg. The prothrombin time was 49 seconds (normal, 20 seconds). The hematocrit was 40.0, and the non-protein nitrogen 17 mg. per 100 cc.

The patient's condition became progressively worse. She was nauseated, retched considerably and vomited occasionally. She was given daily intravenous dextrose and repeated transfusions. On the sixteenth hospital day the van den Bergh was 8.2 mg. direct, and 13.8 mg. indirect. The stools became guaiac positive. The urine gave a +++ test for albumin and a ++ test for bile, and was positive for tyrosine crystals (Morner's test).

She died on the eighteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. MARIAN ROPES: May we see the x-ray films?

DR. GEORGE W. HOLMES: The gallstones are obvious. The position of the gallstones gives some idea concerning the position of the lower border of the liver. You can vaguely make out the liver shadow. It is not enlarged so far as I can see, nor abnormal in shape. In this film the diaphragm seems to be quite high on the right side so that even though the lower border is not unusually low, the liver might still be somewhat enlarged. It is also possible that the film was taken at the end of expiration rather than of inspiration. I see nothing abnormal in the lung fields. The heart shadow is well within normal limits, both in size and shape.

As I understand the story the patient received radium treatment and was said to have had proctitis following it. Apparently an effort was made to study the rectum and lower sigmoid by means of a barium enema, a rather careful search having been made for any abnormality in that region, but I should say that this is a rather normal looking colon throughout. We have some films of the stomach, including the duodenal loop, that appear to be normal. In the cases with serious complication following heavy radiation to the pelvis, the organ most likely to be injured is the small bowel. Patients will stand a good deal of injury to the large bowel and recover, but the same amount of injury to the small bowel often causes considerable difficulty. There is no indication here of such injury — no collection of gas and no dilated loops of small bowel suggesting obstruction, such as might occur after heavy radiation.

DR. ROPES: This case presents a picture with various confusing features. It is apparent that the patient had severe liver-cell damage, and it is also probable that she had some obstruction to the biliary

flow. I judge that her death was due fundamentally to the liver damage. The underlying etiology and sequence of events leading to this final picture, however, are not equally clear. Various etiologic possibilities should be considered. A malignant neoplasm, either primary or secondary in the liver, or primary in any part of the biliary system, seems unlikely in view of the rapid course of the disease, the variation in jaundice, and the marked evidence of liver-cell damage. Pylephlebitis, idiopathic hepatitis, cholangitis, cholelithiasis and cholecystitis should be considered. Before discussing these possibilities however, it might be well to summarize the evidence indicative of the extent to which the jaundice was due to liver-cell damage and the extent to which obstruction may have played a role.

The clinical evidence gave little information in this respect except the fact that bile in some quantity reached the gastrointestinal tract at all times during the disease, with resulting tan or brown stools and with normal bilirubin in the urine. In the laboratory evidence one finds definite indication of liver damage as indicated by the tyrosine crystals in the urine; the high cephalin flocculation test is presumably further indication of severe liver-cell damage, as is perhaps the leukopenia. The low globulin is a surprising finding and helps me not at all in differentiation in this respect. The exceptionally high bromsulfalein retention would not have been found unless there had been severe liver-cell damage, even if obstruction were present. The van den Bergh gives a suggestion of obstruction to biliary flow. A high direct van den Bergh, particularly as high as it was in this case, is unlikely in pure parenchymatous liver disease. I am told that a direct-indirect ratio of 60 to 80 — this patient had 70 — is suggestive of obstruction, whereas in pure parenchymatous liver disease the ratio rarely goes over 50. How well corroborated that is, I do not know.

With this evidence I should like to return to the etiologic possibilities. Pylephlebitis must be considered. It is intriguing to consider whether one could thereby relate the pelvic inflammation — the pyometrium — to the present illness. It would be unusual to have an asymptomatic period of six months, and an absence of fever and leukocytosis. The marked evidence of liver damage is difficult to explain on the basis of pylephlebitis. Idiopathic hepatitis and cholangitis would explain most of the picture. The early onset of pain in the right upper quadrant and the recurrent attacks of moderately severe colicky pain are unusual in this condition but not entirely inconsistent with it. The gallstones cannot be overlooked. So far as we know, they were rather large and presumably in the gall bladder. Gallstones, particularly if in the common duct, with some obstruction and with some cholangitis, could form the basis for this terminal picture. The presence of the splenomegaly raises the question of an

underlying cirrhosis. I believe, however, that the enlargement of the spleen could be ascribed to the severe liver damage. The tender large liver — at least clinically large — and the large spleen are consistent with pylephlebitis, with idiopathic hepatitis or with hepatitis associated with cholelithiasis.

In conclusion I think that this patient had severe parenchymatous liver disease and that she also had cholelithiasis. Whether the former could in any way be related to the latter etiologically, I do not know. It seems somewhat improbable. I also doubt that she had pylephlebitis as an underlying cause of the severe liver disease.

DR. J. H. MEANS: I saw this patient every day while she was in the hospital and followed her carefully. Our line of reasoning followed Dr. Ropes almost exactly and led to the same diagnosis. We believed that she died of severe parenchymatous liver disease, a hepatitis of some sort. We did not know of what variety. We also tried to connect it with the pelvic sepsis and wondered if she had pylephlebitis, but in my note I stated that I thought that that was unlikely because she had had a considerable interval of good health in between. The question of cirrhosis was considered. The size of the spleen was interesting. I thought the liver was enlarged when she first came in, and I am interested to know what the pathologist has to say about that. The clinician and radiologist often have different views about the size of the liver, but the pathologist is able to settle the matter because he can weigh it. I thought that the liver was firm and smooth but could not feel a definite edge.

The impressive thing on the ward was the steady downhill course, the patient becoming sicker and sicker every day in spite of all we could do. Dr. Chester M. Jones saw her several times, and Dr. Arthur W. Allen was asked to see her because the question arose whether she should be explored, but that was decided against. Dr. Jones laid a great deal of weight on the color of the stools. Indeed, he said to me one day, "If the stools remain brown, do not let the surgeons do a laparotomy." They remained brown, and the surgeons did not want to do a laparotomy. We thought that the gallstones had little or nothing to do with the picture in all probability. She had not taken any medicine that we could recognize as a liver toxin, so we called it hepatitis of unknown origin. We did think at the end that she might have had acute yellow atrophy, although we could not prove it. We also thought of the possibility of an acute yellow atrophy that supervened on a cirrhotic liver but could not establish that diagnosis.

DR. JACOB LERMAN: Did the liver change in size?

DR. MEANS: I cannot answer that. I do not know that we proved that it did.

DR. PAUL ZAMECNIK: Was catarrhal jaundice considered?

DR. MEANS: Yes, at entry. She did not appear to be particularly sick and we thought that that was a reasonable diagnosis to consider. The blood picture was consistent with it. In fact she was almost too well to have catarrhal jaundice. She rapidly became sicker and sicker and we abandoned that diagnosis as inadequate.

DR. ZAMECNIK: It is occasionally followed by hepatitis.

DR. MEANS: That is true. Catarrhal jaundice is hepatitis, is it not? It is really just a matter of degree. We wondered when she died if we had treated her adequately. We had given her a diet low in fat and high in everything else, pushed with vigor. Dr. Jones thought that we had done everything possible.

CLINICAL DIAGNOSES

Intrahepatic disease.
Acute yellow atrophy?
Cholelithiasis.

DR. ROPES'S DIAGNOSES

Parenchymatous liver disease.
Cholelithiasis.

ANATOMICAL DIAGNOSES

Subacute yellow atrophy of liver.
Splenomegaly.
Ascites.
Cholelithiasis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy showed a liver of normal size, weighing 1400 gm. It was greenish brown and extremely friable; as one touched it, it broke. It had on the surface a few elevations, as if some attempt at regeneration had occurred. From the gross appearance we thought that it was an acute yellow atrophy of the liver.

Microscopic examination showed that practically all the liver cells had been destroyed. There were a few small islands of regeneration, so that this was perhaps a subacute yellow atrophy. The point that Dr. Means brought out — namely, that catarrhal jaundice is merely a mild form of acute yellow atrophy — is probably correct. We believe that it is exactly the same disease. Aspiration biopsies of the livers of patients ill with catarrhal jaundice have shown diffuse hepatitis, with inflammatory cells in the early stages, followed by areas of necrosis and finally by connective-tissue proliferation.¹ If the disease is not severe, the patient gets well; if severe, death is due to acute yellow atrophy or subacute yellow atrophy, depending on how long the course runs.

The spleen was enlarged, weighing 550 gm., the usual finding in atrophy of the liver. There were

forced to sit up. There was profuse sweating. This episode presumably lasted for a few minutes. The temperature was 100°F., the pulse 96, and the respirations 24. The white-cell count was 5200, with 82 per cent neutrophils. The urine had a + test for albumin and a ++ test for bile. The stools became brown and remained so. The direct van den Bergh was 12.7 mg., the indirect 17 mg. The prothrombin time was 49 seconds (normal, 20 seconds). The hematocrit was 40.0, and the non-protein nitrogen 17 mg. per 100 cc.

The patient's condition became progressively worse. She was nauseated, retched considerably and vomited occasionally. She was given daily intravenous dextrose and repeated transfusions. On the sixteenth hospital day the van den Bergh was 8.2 mg. direct, and 13.8 mg. indirect. The stools became guaiac positive. The urine gave a +++ test for albumin and a ++ test for bile, and was positive for tyrosine crystals (Morner's test).

She died on the eighteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. MARIAN ROPES: May we see the x-ray films?

DR. GEORGE W. HOLMES: The gallstones are obvious. The position of the gallstones gives some idea concerning the position of the lower border of the liver. You can vaguely make out the liver shadow. It is not enlarged so far as I can see, nor abnormal in shape. In this film the diaphragm seems to be quite high on the right side so that even though the lower border is not unusually low, the liver might still be somewhat enlarged. It is intriguing to consider whether it could thereby relate the pelvic inflammation — the pyometrium — to the present illness. It would be unusual to have an asymptomatic period of several months, and an absence of fever and leukocytosis. The marked evidence of liver damage is difficult to explain on the basis of pylephlebitis. Idiopathic hepatitis and cholangitis would explain most of the picture. The early onset of pain in the right upper quadrant and the recurrent attacks of moderate to severe colicky pain are unusual in this condition but not entirely inconsistent with it. The gallstones cannot be overlooked. So far as we know, they were rather large and presumably in the gall bladder. Gallstones, particularly if in the common duct, will cause some obstruction and with some cholangitis, could form the basis for this terminal picture. The presence of the splenomegaly raises the question of

Examination of the blood showed a hemoglobin of 95 per cent, a red-cell count of 4,400,000 and a white-cell count of 7900, with 60 per cent neutrophils. The urine was normal. A blood Hinton test was negative.

Stereoscopic x-ray films of the left shoulder showed the clavicle to be normal. There was a well-defined soft-tissue mass in the supraclavicular area on the left that extended downward behind the clavicle and apparently into the space between the scapula and the chest wall (Fig. 1). This mass showed several flecks of calcification. The lowermost areas of calcification lay close to the undersurface of the scapula. A questionable separate mass was seen in the axilla. The undersurface of the scapula seemed thinned by the mass. X-ray films of the chest, abdomen and long bones showed no evidence of pathology.

An operation was performed on the thirteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. CARROLL B. LARSON: The initial complaint was pain in the left arm at the shoulder, especially on vigorous movement or by pressure on the shoulder. In the subsequent history I am not sure when they say "pain over the shoulder" whether they mean over the scapular joint. It might make a difference.

DR. ROBERT R. LINTON: I believe it was directly over the shoulder.

DR. LARSON: Do you recall whether it was worse at night than during the day, which is characteristic of deep bone pain?

DR. LINTON: I do not believe that it was.

DR. LARSON: Apparently there was no mechanical obstruction to the usual motions of the arm. The fact that he could not throw a ball, however, suggests that there was some difficulty.

This story does not suggest a lesion in the region of the epiphysis or a lesion disturbing the blood supply because of no inequality in arm lengths at the end of a three-year period. The difference in the circumferences of the two arms could have come from lack of use of the left arm rather than from the lack of development.

At rest the arm "was carried with the elbow and wrist in partial flexion." I am not sure what to make of that. It may be possible that, with a mechanical difficulty in the shoulder, such a position was a comfortable one for carrying the arm. The inability to rotate the left shoulder might have been because of pain or mechanical obstruction.

The tremor could be accounted for by lack of muscular development. Anyone with weak muscles cannot sustain a position for any length of time without tremor.

Perhaps we might see the x-ray films at this point. There is a fullness in the supraclavicular region that does look like a "holding forward" of the shoulder,

which gives it a shortening in the anteroposterior view. The joint may or may not be deformed.

DR. MILFORD SCHULZ: The chest is normal except for the deformity of the left shoulder girdle. Here we see the soft-tissue mass extending above the clavicle. These probably are the areas of calcification referred to. In addition one cannot see any bone structure in the body of the scapula. Of course the scapula is normally quite thin in this area, and that may be the reason. From the x-ray films there is no way of knowing whether the calcification is in the soft tissue or represents new-bone formation.

DR. LARSON: The child was perfectly well following the toxin-antitoxin injections. On that basis we

FIGURE 1. Roentgenogram of Left Shoulder Showing Soft-Tissue Mass in Supraclavicular and Subscapular Regions.

can exclude tuberculosis and chronic infection, which might have originated in bone and ended up in a soft-tissue mass giving this picture. The chest was negative and there was no cough or pain referable to the chest, so that we can probably exclude anything coming from the chest.

That leaves us with a tumor in this region but we are not sure whether it arose from bone or from the tissues around the bone. The fact that it was producing symptoms for three years is against a malignant tumor, but does not exclude it. Let us consider the bone tumors that occur in a child of this age.

With Ewing's tumor one would expect more new-bone formation. Lymphoblastoma occurs in this group of children and this is one of the locations which it can occur; frequently the tumor exten-

itself from the bone and produces a soft-tissue mass. In this boy there was little bone destruction compared to the size of the mass. With malignant lymphoma there is usually some clinical evidence of malignant disease, such as cachexia and marked anemia. I cannot, however, exclude lymphoblastoma as a possibility. Giant-cell tumor can be excluded almost immediately. There was not enough bone destruction, and the patient was in the wrong age group. A chondrosarcoma can occur in this area, and there may be areas of calcification within it. The mass may have developed from malignant degeneration in a chondroma. I cannot exclude that. Fibrosarcoma must also be considered. This mass overlay an area where the subscapularis muscle originates, and a soft-tissue tumor like a fibrosarcoma can develop in the subscapularis itself. In a primary nerve tumor one would expect more persistent pain and a greater number of neurologic findings.

Cartilaginous exostoses might fit in with a bone condition of this sort. It is most unusual for exostoses to reach this point of growth without producing more pronounced mechanical symptoms than this boy had, and there should be more evidence of new-bone formation. Hence, I exclude this diagnosis.

That leaves us with malignant tumor, even though the patient did not show constitutional signs of malignancy after three years. I believe that it was of the chondroblastic type, but it might have been fibroblastic or lymphoblastic.

DR. WILLIAM B. BREED: I do not understand whether you believe that the tumor originated in the bone.

DR. LARSON: As I stated before, the decision is difficult. The tumor could have originated in the bone and could have exteriorized itself, or it could have produced the entire x-ray picture by external pressure. I favor the former.

DR. LINTON: We were indefinite in our minds preoperatively concerning where the lesion originated. I rather thought that it was a malignant lesion, which would necessitate a shoulder-girdle amputation. Dr. J. C. White saw the boy because the question of nerve tumor was raised. It was decided that, if the tumor was not malignant, he would try to remove it by lifting the brachial plexus and the supraclavicular vessels. He started the operation by dividing the clavicle and exposing the tumor. It was obvious that the tumor was malignant and I completed the operation by doing a shoulder-girdle amputation and removing the entire clavicle. I did a block dissection and did not try to determine where the tumor had arisen. It was our feeling that it

probably arose from the brachial plexus. Extensive dissection of the cervical lymph nodes was also performed since some of the nodes in the posterior triangle were enlarged and appeared to be involved. The roots of the brachial plexus were divided close to the intervertebral foramina.

CLINICAL DIAGNOSIS

Tumor of clavicle (neurofibroma?).

DR. LARSON'S DIAGNOSIS

Chondrosarcoma of scapula, low grade (possibly fibrosarcoma of subscapular region or lymphoblastoma of scapula).

ANATOMICAL DIAGNOSIS

Neurogenic fibrosarcoma of subscapular region.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The tumor was large and fibrous and measured 14 by 9 by 6 cm. There was erosion of the scapula and of the clavicle, but it seemed to us to be the type of erosion that results from long-standing pressure against bone. There was no direct invasion of bone. The mass did, however, invade some of the surrounding muscles.

Microscopically it was a low-grade neurogenic fibrosarcoma, that probably arose from one of the branches of the brachial plexus. The regional lymph nodes were negative.

DR. LINTON: From the surgical point of view, if it was a low-grade malignant process, such as a fibrosarcoma, I believe that the best thing to have done is what we did.

DR. CASTLEMAN: The boy was seen seven months after operation and was perfectly well, going to school and playing just like any other boy. His only complaint was tenderness in the upper portion of the operative field when it is washed, apparently due to the severed nerve roots close to the skin. Fourteen months after operation, however, the patient re-entered the hospital because of a recurrent nodule in the neck. The mass was located in the upper lateral portion of the operative field; it involved the lower lateral end of the sternal mastoid muscle and was adherent to the first rib. The nodule, which measured 7 by 3 by 3 cm., and the first rib were removed; on microscopical examination it was found to comprise neoplastic tissue identical with that of the original tumor.

SHARE THE BLOOD!

THERE is an urgent, almost dramatic, need for blood donors to furnish plasma for our fighting men, and the medical profession, which should be such a potent factor in promoting this vital enterprise, is, in too many instances, handicapping it. Healthy civilians, both men and women, who need encouragement to give blood at safe and reasonable intervals are being deterred from it, frequently for insufficient reasons. We are not yet awake to our opportunity and our obligation, for the supply is inadequate and the need will soon become desperate as the time for invasion draws near.

A remarkable organization for the collection of human blood plasma has been developed. This was

the result of a request made in May, 1941, by the surgeons general of the Army and Navy to the American Red Cross and the Division of Medical Sciences of the National Research Council. The function of the Red Cross has been to procure the donors, that of the National Research Council to supervise the professional services.¹ Through its various centers, the Red Cross met its quota of 4,000,000 pints of plasma in 1943; this year 5,300,000 pints will be required, and it must be noted that, owing to broken appointments, rejected volunteers and bloods, and certain irreducible technical losses, nearly 1250 persons must offer to give their blood for each 1000 units of dried plasma finally made available.

The blood collecting center in Boston, the only one in northern New England, is equipped to handle, during its six-day, sixty-eight-hour week, 800 donors daily, attaining, at times, a maximum speed of two bleedings per minute. The substation in Lynn and the three mobile units, operating at distances greater than twenty-five miles from Boston, are each equipped to bring in an additional 1000 pints weekly. The actual number of donors bled at the Boston center recently dropped to between 400 and 550 per day, and a large number of these are war workers and service men. The civilian population is not doing its share.

The safety and health of the donor are carefully protected. Each donor must be free from disqualifying disease and must have a normal temperature at the time of bleeding, as well as a hemoglobin level of 80 per cent or over by the Tallqvist method and a systolic blood pressure between 100 and 200. No donor is accepted oftener than five times in a year, with a minimum interval of eight weeks between donations. This interval seems conservative in view of the studies of Fowler and Barer,² who found that the average drop in hemoglobin of 2.3 gm. after the removal of 555 cc. of blood was restored on the average in approximately fifty days, the time being somewhat longer for women than for men, and that the rate of regeneration did not seem to be affected by repeated donations.

Psychic factors in certain persons may be more important deterrents to blood donating than physical ones. Let us all, however, when the oppor-

tunities come to give advice on the subject, weigh the evidence objectively, and encourage rather than discourage, unless we are certain that a person's health may suffer unduly from this act of mercy.

TUBERCULOSIS AND THE WAR

THE effect of war on tuberculosis death rates is generally considered to be inevitable and adverse. Heretofore it has always seemed to be so, although the slight increases in mortality observed in this country in 1917 and 1918 were more than compensated for by the subsequent accentuation of the downward curve. Anticipating that tuberculosis may again be "one of the camp followers of war," a committee of the American Trudeau Society* surveyed the personnel of the sanatoriums in this country and reported a distinct reduction during 1942. It is certain that this decrease in numbers, continuing on through 1943, is placing an ever-increasing burden on those who are left to operate the sanatoriums.

The war is also having an effect on the symbiotic relations between man and the tubercle bacillus. The armed services are rejecting, and thereby uncovering, many of the dangerous carriers among young men — those whose disease is symptomless but who nevertheless have open lesions from which they may freshly expose and widely spread the infection. From the millions of men examined at the induction stations, it is estimated that 25,000 had been diagnosed at the end of last year to have a disease that neither they nor their friends would have suspected under prewar conditions. And how are these patients, many of whom need sanatorium treatment, going to be accommodated by the currently restricted personnel of the sanatoriums?

Tuberculosis workers, who for some years past have been extending their case-finding activities, are thus suddenly having found for them more cases than they can conveniently care for. Morbidity

**Personal Problems of Sanatoria Resulting from War Conditions*. Report of a study made by the Committee on Sanatorium Standards, American Trudeau Society. 39 pp. New York: National Tuberculosis Association, 1943.

rates should go up, but there will not be more actual sickness — it will merely be more completely recognized. The mortality rates need not go up at all, for most of the cases will do as well as they would have if they had not been recognized, and many of them do better. Furthermore, fewer contacts will result.

No evidence has yet been uncovered to indicate that the downward trend of the tuberculosis death rate has been seriously affected. Whether it will be adversely influenced by a prolonged continuation of the war is a purely relative matter, and is really an insignificant speculation in comparison to the total interests similarly involved. On the whole it seems that the war will accelerate the antituberculosis effort by forcing a decreased personnel to dedicate itself to an increased volume of labor: just as the training of doctors and engineers is being accelerated, just as the shipbuilders are launching an incredibly large number of ships, and just as the entire nation is bending itself to the task ahead. The *Journal* has sufficient confidence in all the forces involved to make a humble prediction that the war years will not show an increase in the mortality of tuberculosis in the United States. This statement is not a mere prophecy — it is an expression of confidence in the ability, ingenuity and steadfast qualities of those who specialize in the care and the cure of tuberculosis.

MEDICAL EPONYM

RUMPEL-LEEDE SIGN

Theodor Rumpel (1862-1923), director of the Barmbecker Krankenhaus in Hamburg and chief physician of the Second Medical Service of the Allgemeines Krankenhaus, presented "Photographien von Scharlachkranken mit multiplen Hautblutungen [Photographs of Scarlet-Fever Patients with Multiple Skin Hemorrhages]" at a meeting of the Aerztlicher Verein in Hamburg on June 1, 1909. A report appears in the *Deutsche medizinische Wochenschrift* (35:2297, 1909). A portion of the translation follows:

These hemorrhages, which also occur spontaneously on the forearm and in the bend of the elbow, in the area where the exanthem is most marked, may be induced by mechanical stimuli, particularly by the application of Bier's compression cuff to the upper arm, and are then of value in the differential diagnosis of scarlet fever.

Carl S. Leede (b. 1882), then assistant to Professor Rumpel and later a practitioner of internal medicine in Seattle, Washington, described "Hautblutungen durch Stauung hervorgerufen als diagnostisches Hilfsmittel beim Scharlach [Skin Hemorrhages Elicited by Congestion as a Diagnostic Aid in Scarlet Fever]" in the *Münchener medizinische Wochenschrift* (58:293-295, 1911). A portion of the translation follows:

At the request of [my] chief, Dr. Rumpel, who directed attention to the differential diagnostic significance of the phenomenon at the meeting of the medical society June 13, 1909, every case of scarlet fever was systematically subject to congestion by means of a rubber cuff applied to the upper arm so that the veins stood out distinctly while the pulse remained palpable.

Hereupon, almost without exception, among cases of scarlet fever (several hundred were examined) more or less marked skin hemorrhages appeared. . . .

In my experience a *negative* result of the congestion test may be used as an almost certain criterion against scarlet fever, whereas a *positive* result may be evaluated only together with other symptoms.

We perform the congestion test at the present time as follows:

A broad rubber cuff is placed about the upper arm above the elbow so that the veins stand out distinctly; the hand becomes blue, but the pulse remains palpable. After ten to fifteen minutes we loosen the cuff and examine the tender skin of the fold of the elbow, at the same time making the skin anemic by means of stretching it, whereupon the petechiae stand out more distinctly as a dark spray.

We call the congestion test positive even though we find only a moderate number of petechiae.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

PERLEY — Roseoe D. Perley, M.D., of Melrose, died January 21. He was in his eighty-first year.

Dr. Perley received his degree from Harvard Medical School in 1896. He was a former member of the staffs of the Massachusetts General Hospital and the Boston Lying-in Hospital and was on the surgical staff of the Melrose Hospital for forty years. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son and a daughter survive.

RICH — Herbert L. Rich, M.D., of Attleboro, died January 23. He was in his seventy-ninth year.

Dr. Rich received his degree from Tufts College Medical School in 1898. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow and a brother survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CHANCROID, GRANULOMA INGUINALE AND LYMPHOGRANULOMA VENEREUM MADE REPORTABLE

As provided by the General Laws, Chapter III, Section 6, the Department of Public Health has defined and made reportable the diseases *chancroid*, *granuloma inguinale* and *lymphogranuloma venereum*. Physicians in Massachusetts are required to report these diseases directly to the De-

partment of Public Health under the same conditions, rules and regulations as now pertain to the reporting of syphilis and gonorrhea; and further, to use the same report form that is now provided by the department to report syphilis and gonorrhea for the purpose of reporting these three other diseases. For the present, it is suggested that the physician write on the report form the name of the disease he is reporting and strike out the words, "syphilis" and "gonorrhea."

Prepared spreads of material collected from the undermined edges of the suspected chancroidal ulceration or, still better, from the aspirated pus of the bubo may be submitted by the physician to the Bacteriological Laboratory, State House, Boston, for diagnosis. A spread of macerated tissue from the active edge of a lesion thought to be granuloma inguinale may also be sent to the laboratory. Antigen for skin testing for lymphogranuloma venereum will soon be available from the Antitoxin and Vaccine Laboratory for free distribution to private physicians. Literature dealing in detail with the management of these diseases by the physician may be obtained from the Department of Public Health.

MISCELLANY

THE ELLA SACHS PLOTZ FOUNDATION

During the twentieth year of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation, eighteen applications for grants were received by the trustees, thirteen of which came from the United States, the other five coming from five different countries in Europe, Asia, North and South America. In the twenty years of its existence the Foundation has made four hundred and eighty-one grants which have been distributed to scientists throughout the world.

In their first statement regarding the purposes for which the fund would be used, the trustees expressed themselves as follows:

1. For the present, researches will be favored that are directed toward the solution of problems in medicine and surgery or in branches of science bearing on medicine and surgery.
2. As a rule, preference will be given to researches on a single problem or on closely allied problems. It is hoped that investigators in this and in other countries may be found, whose work on similar or related problems may be assisted so that more rapid progress may be made possible.
3. Grants may be used for the purchase of apparatus and supplies that include the payment of unusual salaries, including technical assistants, which are, ordinarily, not provided for by the support of exceptional circumstances.

In the past few years the policy outlined in paragraph 2 has been neglected. Grants will be given in the sciences closely related to medicine without reference to special fields. The maximum size of grants will usually be less than \$500.

Applications for grants to be held during the year 1944-1945 must be in the hands of the committee before April, 1944. There are no formal application blanks but letters asking for aid must state definitely the qualifications of the investigator, an accurate description of the research, the size of the grant requested and the specific use of the money to be expended. In their requests for aid applicants should state whether or not they have approached other foundations for financial assistance. It is highly desirable to include letters of recommendation from the directors of the departments in which the work is to be done. Only applications complying with the above conditions will be considered.

Applications should be sent to Dr. Joseph C. Aub, Massachusetts General Hospital, Fruit Street, Boston.

CORRESPONDENCE

APPEAL FOR BOOKS

To the Editor: This is a personal appeal. We need your help. The National Victory Book Campaign terminated on December 31, 1943. An unfortunate impression has become current, that the campaign was wound up because it had collected all the books needed. Nothing could be further from the facts. — The men in our armed forces and in the Merchant Marine need books *desperately*.

The Massachusetts Victory Book Committee has been formed to carry on in Massachusetts from where the National Victory Book Campaign left off. The Massachusetts Committee has set its minimum goal at 250,000 volumes. All types of books, in good condition, are welcome. Biographies, travel, science, religion, but especially good fiction — mysteries, westerns and comics — are in demand. Visualize how men on long sea voyages, on dreary coast patrols, in lonely outposts and in the remote parts of the world yearn for something to read.

The Massachusetts Victory Book Committee needs your help. It asks you personally and in your official capacity to enlist the wholehearted efforts of your readers.

Every book donated will reach the armed forces where it is most wanted. Distribution will be handled by Special Service officers of the Army and the Welfare officers of the Navy. The merchant-marine and the Red Cross military hospitals will also receive their share.

You are familiar with the slogan "Get the Vote Out." This committee's slogan is "Get the Books Out." It is a big job, but it must be done.

Books should be left at local public libraries or at the nearest Information Center of the Massachusetts Committee on Public Safety. This committee will do the rest.

JOHN HEARD, *Secretary*
Massachusetts Victory Book Committee

13 Commonwealth Avenue
Boston 16

NOTICES

UROLOGY AWARD

The American Urological Association offers an annual award "not to exceed \$500" for an essay (or essays) on the result of some specific clinical or laboratory research in urology. The amount of the prize is based on the merits of the work presented, and if the members of the Committee on Scientific Research deem none of the offerings worthy, no award will be made. Competitors shall be limited to residents in urology in recognized hospitals and to urologists who have been in such specific practice for not more than five years. All interested should write the secretary for full particulars.

The selected essay (or essays) will appear on the program of the forthcoming meeting of the American Urological Association, June 19-22, 1944, Hotel Jefferson, St. Louis, Missouri.

Essays must be in the hands of the secretary, Dr. Thomas D. Moore, 899 Madison Avenue, Memphis, Tennessee, on or before March 15, 1944.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, February 3, in the classroom of the Nurses' Residence, at 7:15 p.m. Dr. Francis L. Weille will speak on the subject "Treatment of Sinusitis." Dr. Elizabeth DeBlois will be chairman.

JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston

Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

Wednesday, February 2 — To be announced. Dr. John D. Adams.

Friday, February 4 — Clinical Importance of Cold Hemagglutinins. Dr. Cutting B. Favour.

Wednesday, February 9 — The Diagnosis of Pancreatic Disease. Dr. Joseph H. Pratt.

Friday, February 11 — Clinicopathological conference. Dr. Chester S. Kcfer and Dr. Harold E. McMahon.

Wednesday, February 16 — Constipation. Dr. Edwin T. Whitney.

Friday, February 18 — Some Postwar Aspects of Malaria. Dr. William C. McCarthy.

Wednesday, February 23 — Mechanisms Predisposing to Pneumonia. Dr. Dwight O'Hara.

Friday, February 25 — Visualization of the Biliary Tract. Dr. Charles G. Mixer.

On Tuesday and Thursday mornings Dr. S. J. Thannhauser will give medical clinics on hospital cases.

WASHINGTONIAN HOSPITAL

The second lecture in a series on various aspects of alcoholism, arranged by the Washingtonian Hospital and being given under its auspices and that of the Committee on Alcoholism of the Boston Council of Social Agencies, will be held at Zero Marlborough Street, Boston, at 7:30 on Friday evening, February 11. The speaker will be Dwight Anderson, LL.B., director, Public Relations, Medical Society of the State of New York, and his topic, "Alcohol and Public Opinion."

NEW ENGLAND DERMATOLOGICAL SOCIETY

The regular meeting of the New England Dermatological Society will be held in the Skin Out Patient Department of the Massachusetts General Hospital on Wednesday, February 9, at 2 p.m.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, FEBRUARY 3

THURSDAY, FEBRUARY 3

*9.00-10.00 a.m. Medical clinic. Dr. S. J. Thannhauser, Joseph H. Pratt Diagnostic Hospital.

7:15 p.m. Treatment of Sinusitis. Dr. Francis L. Weille. New England Hospital for Women and Children.

FRIDAY, FEBRUARY 4

*9.00-10.00 a.m. Clinical Importance of Cold Hemagglutinins. Dr. Cutting B. Favour. Joseph H. Pratt Diagnostic Hospital.

SATURDAY, FEBRUARY 5

*10.00-11.30 a.m. Medical staff rounds. Peter Bent Brigham Hospital.

Number 5

PERITONEOSCOPY IN LIVER DISEASE*

EDWARD B. BENEDICT, M.D.†

BOSTON

IN a series of 435 peritoneoscopies¹⁻³ performed during the last few years at the Massachusetts General Hospital, the question of liver disease arose in 331, or 70 per cent, of the cases examined. The instrument designed by Ruddock^{4, 5} was used in all cases. It is therefore evident that one of the chief uses of the peritoneoscope is in the diagnosis of liver disease.

When one considers that many of these patients are seriously ill and that in most of them an exploratory laparotomy is out of the question, the value of a precise diagnosis by peritoneoscopy is apparent. In comparing peritoneoscopy with exploration it should be pointed out that the former procedure requires only a 1-cm. incision under local anesthesia, an overnight stay in the hospital and minimum risk or discomfort to the patient. In 435 peritoneoscopies there have been 3 deaths (0.73 per cent) probably attributable to the procedure: one, a death from heart failure in a patient with multiple lung abscesses, coronary disease and possible echinococcal cyst of the liver; the second, a death due in part to hemorrhage eight days after peritoneoscopy with liver biopsy for extensive metastatic carcinoma; and the third, a death three weeks after perforation of the large bowel in a severely ill patient proved by peritoneoscopy to have advanced tuberculous peritonitis. These patients were all extremely sick, and it was probably unwise to subject the first one to peritoneoscopy, but many very sick patients can safely undergo the procedure if carefully watched by a competent assistant.

The preparation of the patient with liver disease for peritoneoscopy is of considerable importance, for frequently there is jaundice and liver damage. If the prothrombin time is prolonged, vitamin K is administered to reduce the bleeding tendency. Morphine and its derivatives, as well as the barbiturates, are to be avoided. Chloral hydrate may be safely substituted. Otherwise the patient is prepared as for any laparotomy, including an abdominal shave and scrub, and emptying of the stomach and

bladder. The usual site of puncture for inspection of the liver is in the midline just above the umbilicus. The technic of the procedure has been described in previous reports.¹⁻⁵

In a general way the cases of liver disease may be divided into two groups—the malignant and the nonmalignant. The 260 cases of liver disease in this series were classified as shown in Table 1.

TABLE 1. Classification of Cases of Liver Disease.

MALIGNANT		NONMALIGNANT	
Metastatic carcinoma	170	Cirrhosis	73
Primary carcinoma	5	Cholangitis	22
Melanotic sarcoma	1	Banti's disease	2
Malignant lymphoma	1	Lymphangioma	2
Total	177	Polycystic liver	1
		Echinococcal cyst.	1
		Sarcoid	1
		Enlarged liver	1
		Total	83

In the remaining 71 cases there was found to be an essentially normal liver. From the above tabulation it is evident that carcinoma and cirrhosis are by far the commonest diagnoses. So the question often to be decided by peritoneoscopy is the following: Is there any disease in the liver and, if so, is it cancer, cirrhosis or something unsuspected?

The cases referred for peritoneoscopy because of liver disease usually fall into one of the following groups:

Metastatic carcinoma. In this group there is a positive or presumptive clinical diagnosis of carcinoma of the breast, bronchus, esophagus, stomach, pancreas, colon, rectum, prostate or the like, and before planning medical, x-ray or surgical treatment it may be of great importance to know whether or not there is metastatic disease in the liver.

Hepatomegaly. Is one dealing with metastatic or primary carcinoma, cirrhosis, hepatitis, sarcoma, echinococcal cyst, polycystic liver or some other liver disease?

Ascites. Is this due to cirrhosis, carcinoma or tuberculous peritonitis?

Jaundice. Is the diagnosis toxic cirrhosis, biliary cirrhosis, malignant neoplasm, hepatitis or some other infectious process?

*From the Massachusetts General Hospital.
†Instructor in surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital.

Doubtful clinical findings. What is the precise diagnosis?

Primary carcinoma of liver.

Metastatic Carcinoma

In this group the primary source is oftener in the stomach than in any of the other organs. Peritoneoscopy was performed in 95 cases of carcinoma of the stomach, 75 of which showed no metastases and 20 of which did show metastases. Thus, a laparotomy was avoided in 20 cases (21 per cent). During a five-year period (1937-1941), 263 patients with cancer of the stomach were explored surgically without peritoneoscopy and in 39, or 15 per cent, the cases were found to be inoperable because of liver metastases. If peritoneoscopy had been performed in these cases, thirty-nine laparotomies might have been avoided and over a year in hospital days saved.

CASE 1. J. K., (M.G.H. U-334286), a 56-year-old Russian porter, was first admitted to the hospital complaining of abdominal pain of 5 weeks' duration, associated with anorexia, nausea, vomiting and a weight loss of 15 pounds during the previous 6 weeks.

Physical examination showed slight resistance and tenderness in the epigastrium. There was no palpable mass and the liver was not felt. A large carcinoma of the stomach was reported by x-ray.

Peritoneoscopy revealed several yellow, umbilicated lesions in the liver, characteristic of metastatic carcinoma. Numerous, small nodules were seen on the anterior surface of the stomach consistent with carcinomatous invasion of the serosal surface. A biopsy was obtained from one of the lesions in the liver. The pathological report was metastatic carcinoma. Laparotomy was therefore not done.

Clinically this case was operable. The patient was only fifty-six years old and was well developed and nourished, and no abdominal mass was palpable. Except for the positive evidence of metastatic cancer in the liver at peritoneoscopy, he would probably have been subjected to a fruitless exploratory laparotomy.

If, on the other hand, no metastatic disease is demonstrable by peritoneoscopy, the patient should be explored surgically. Sometimes, as in the following case, when a patient appears clinically to be inoperable a favorable peritoneoscopy report encourages a successful resection.

CASE 2. M. J. (M.G.H. U-99960), a 77-year-old, unemployed Irishman, was admitted to the hospital complaining of indigestion and an abdominal lump. He had been perfectly well until 3 months before admission, when he gradually developed epigastric distress and soreness after meals. Four weeks previously he had noted a lump in the epigastrium.

Physical examination disclosed a midepigastric, apple-sized movable mass. X-ray examination showed extensive cancer of the distal half of the stomach.

Peritoneoscopy revealed a normal liver and no evidence of peritoneal metastases or of extension of the growth through the gastric wall. Operation was therefore undertaken, and although there were carcinomatous lymph nodes along the lesser curvature, a gastric resection was successfully carried out.

In addition to cancer of the liver metastatic from the stomach, peritoneoscopy has in many cases demonstrated metastatic disease in the liver when

the primary source was in the breast, bronchus, esophagus, pancreas, colon, rectum or prostate or was of undetermined origin. In some of these cases, exploratory operation was thus avoided.

Hepatomegaly

CASE 3. G. S. R. (B.M. U-389474), a 35-year-old lumber salesman, entered the hospital because of enlargement of the abdomen of 1 week's duration. For 12 years there had been an excessive intake of alcohol, with anorexia for 6 months. There had been a recent 10-pound weight loss.

Physical examination showed jaundice, enlargement of the liver to below the umbilicus and ascites. The temperature varied from 98 to 102°F. A clinical diagnosis of alcoholic cirrhosis was made but, because of the large liver and the fever, malignancy was also considered.

Peritoneoscopy showed a granular, slightly nodular liver of mottled brown, red and yellow color. There was no evidence of malignancy. A biopsy resulted in a diagnosis of cirrhosis, alcoholic type.

In this case of hepatomegaly with jaundice, ascites and weight loss, peritoneoscopy confirmed the clinical diagnosis of alcoholic cirrhosis and excluded carcinoma.

CASE 4. F. H. S. (B.M. U-305683), a 71-year-old man, was referred to the hospital with a diagnosis of carcinoma of the stomach. He gave a history of anorexia and a 25-pound weight loss of 3 months' duration. There was also increasing fatigue and left-sided gas pain occurring 1 to 2 hours after meals.

Physical examination showed a small, elderly man with evidence of recent weight loss. The left lobe of the liver appeared to be enlarged. X-ray examination showed rigidity of the middle third of the lesser curvature of the stomach with narrowing of the antrum. The findings were those of carcinoma of the middle third of the stomach.

Peritoneoscopy was advised to determine whether or not metastases were present in the liver. Contrary to expectation, it showed a granular, almost hobnail liver, suggestive of cirrhosis. A small amount of ascitic fluid was also found and aspirated. A biopsy of the liver resulted in a diagnosis of toxic cirrhosis. Because of these findings no operation was performed. About 3 months later the patient died, and autopsy showed carcinoma of the stomach with metastases to the retroperitoneal and mesenteric lymph nodes and to the peritoneum, advanced portal cirrhosis of the liver, acute generalized fibrinous peritonitis, ascites and arteriosclerosis.

This case is presented to show how peritoneoscopy revealed an unsuspected cirrhosis of the liver in a patient known to have carcinoma of the stomach. Laparotomy was avoided.

CASE 5. I. M. P. (M.G.H. U-309910), a 60-year-old Negro, entered the hospital because of weakness and discomfort in the epigastrium for 4 months.

Physical examination was essentially negative except for a smooth, firm mass in the epigastrium and the right upper quadrant of the abdomen, which was thought to be liver. Differential diagnoses by various members of the staff included metastatic carcinoma, cirrhosis, syphilis, melanotic sarcoma, lymphoma, hemachromatosis, amyloid disease and echinococcal cyst. Various laboratory and x-ray studies failed to give a positive diagnosis.

Peritoneoscopy showed the liver edge to be sharp but somewhat thick. The surface was granular and reddish brown. There was no evidence of malignancy. A biopsy resulted in a diagnosis of nonspecific hepatitis. One month later, when the patient was seen in the Out Patient Department, she was feeling well, her appetite was good, and the liver was still enlarged.

In this case of hepatomegaly, peritoneoscopy explained the enlarged liver by a positive diagnosis of hepatitis.

Certain other cases of hepatomegaly are of interest and may be included in this group. Briefly summarized, they are as follows:

CASE 6. M. G. T. (M.G.H. U-286198), a 71-year-old woman, was admitted with masses in both upper quadrants thought to be an enlarged spleen and liver. The clinical diagnosis was possible acute disseminated lupus or possible Gaucher's spleenomegaly.

Peritoneoscopy showed masses in both upper quadrants due to extensive metastatic carcinoma involving both lobes of the liver. The biopsy report was metastatic adenocarcinoma.

CASE 7. E. E. (M.G.H. U-202726), a 52-year-old woman, was admitted complaining of anorexia and abdominal discomfort. A deep-lying, hard, nodular mass in the right upper quadrant and the epigastrium was clinically diagnosed as retroperitoneal sarcoma or an enlarged liver.

Peritoneoscopy demonstrated extensive carcinomatous implants in the liver. The biopsy report was metastatic adenocarcinoma.

CASE 8. O. L. (M.G.H. U-179499), a 60-year-old man with a history of extreme alcoholism, was admitted complaining of epigastric pain and tenderness. A hard, tender mass was found in the right upper quadrant. The clinical diagnosis was possible cirrhosis, or possible lymphoma.

Peritoneoscopy revealed extensive carcinoma of the liver. The biopsy report was metastatic adenocarcinoma, with the primary source not determined.

CASE 9. J. F. M. (M.G.H. U-360839), a 57-year-old woman, entered the hospital with a history of easy fatigue, dyspnea, cough, nausea and vomiting. The liver was not palpable to several examiners, each of whom reported that he was unable to make a diagnosis. Another observer, however, thought the liver was enlarged, with some epigastric tenderness. X-ray examination confirmed a diagnosis of enlargement of the liver.

Peritoneoscopy revealed a liver filled with umbilicated, yellow nodules characteristic of carcinoma. The biopsy report was metastatic adenocarcinoma, Grade 3.

CASE 10. N. L., A 30-year-old, alcoholic man, entered the hospital because of an enormous liver that he himself had felt. The presumptive diagnosis was cirrhosis.

Peritoneoscopy, however, showed no evidence of cirrhosis, but demonstrated that the anterior surface of both lobes contained numerous slightly elevated, smooth, rounded, yellowish-gray lesions from 1 to 3 cm. in diameter, consistent with metastatic carcinoma, although not typically nodular or umbilicated. The biopsy report was lymphosarcoma.

In the last case, the clinical diagnosis of alcoholic cirrhosis was changed by peritoneoscopy, and the presumptive peritoneoscopic diagnosis of carcinoma was changed by biopsy to lymphosarcoma.

Ascsites

CASE 11. L. L. (M.G.H. U-340612), a 55-year-old, Italian-born laborer, entered the hospital because of progressive enlargement of the abdomen of 2 months' duration, associated with anorexia and a dull pain in the left upper quadrant. All his life he had drunk two glasses of wine a day.

Physical examination revealed a greatly distended abdomen with slightly dilated superficial veins. A fluid wave was present. The liver was palpable about 8 cm. below the costal margin. The tip of the spleen was felt to descend to the iliac crest. There was also a hard, palpable, semicircular mass in the rectum 2 cm. above the prostate. The clinical diagnosis was cirrhosis of the liver, but carcinoma of the rectum with secondary implants in the liver was also considered.

At peritoneoscopy 7000 cc. of cloudy, yellow fluid was aspirated. The peritoneal surfaces throughout the abdomen

were covered with gelatinous, tapioca-like, nodular, translucent material, characteristic of metastatic carcinoma. The liver edge appeared sharp and the surface did not appear cirrhotic. The latter was, however, partially covered with numerous translucent, metastatic lesions that did not appear to involve the parenchyma. The liver edge was at the costal margin. The palpable masses were neither the liver nor the spleen but were large, carcinomatous masses, probably involving the omentum. A biopsy at the peritoneum resulted in a diagnosis of metastatic colloid carcinoma.

In this patient with marked ascites and upper abdominal masses thought to be liver or spleen, the clinical diagnosis was alcoholic cirrhosis, but peritoneoscopy revealed a generalized carcinomatosis.

CASE 12. B. V. D. (B.M. U-395034), a 29-year-old unmarried woman, entered the hospital because of swelling of the abdomen of 2 months' duration. For 9 months her appetite had been poor. For about a year she had noted that she was easily fatigued and had not felt well enough to work. For many years she had taken large amounts of alcohol, including a quart of sherry daily, as well as some brandy.

On physical examination the liver was found to be markedly enlarged, extending 5 fingerbreadths below the costal margin. The spleen was also palpable about three fingerbreadths below the costal border. There was moderate ascites but no jaundice. The presumptive diagnosis was alcoholic cirrhosis.

Peritoneoscopy confirmed this diagnosis and showed the liver to be pale, mottled and yellow. A biopsy of the liver resulted in diagnosis of acute alcoholic cirrhosis.

The patient was kept in the hospital for over a month, receiving h-protein and high-vitamin diet, several blood transfusions. The liver, spleen and the spleen hardly palpable. Peritoneoscopy was repeated at the end of 1 month's treatment, at which time the liver appeared essentially normal in size, with a brownish-red surface. A second biopsy showed less fat and definitely more fibrous tissue. Alcoholic hyalin was still present, but the process was much less acute.

In this case of moderate ascites with a presumptive diagnosis of alcoholic cirrhosis, peritoneoscopy gave positive confirmation of this diagnosis and when repeated at the end of a month demonstrated definite improvement as a result of treatment.

Other cases in this group in which ascites was a marked feature and in which the differential diagnosis of liver disease always presented itself may be briefly mentioned as follows:

CASE 13. O. N. (B.M. U-338963), a 41-year-old man, had ascites and hepatomegaly. Following resection of carcinoma of the sigmoid, x-ray examination demonstrated an enlarged liver and spleen with esophageal varices, making a clinical diagnosis of cirrhosis likely, although metastatic carcinoma was also a strong possibility.

Peritoneoscopy showed extensive carcinomatous implants in the liver and some possible implants on the peritoneum. A biopsy of the liver resulted in a diagnosis of metastatic adenocarcinoma.

This case was most unusual. In spite of the demonstration of esophageal varices, metastatic cancer of the liver rather than cirrhosis, was present.

CASE 14. H. G. (M.G.H. U-389058), a 62-year-old woman, had a history of diarrhea, loss of weight, anorexia and vomiting for 2 months. Physical examination showed the abdomen to be distended with fluid and a large, nodular mass in the epigastrium. Proctoscopy showed a nodular lesion, entirely submucosal. At peritoneoscopy 1500 cc. of yellow, blood-tinged fluid was aspirated. Because of a large omental mass, only a part of the liver could be seen, the anterior surface of

which appeared entirely normal. A large, pearly-gray mass with numerous excrescences on it was seen in the lower abdomen and pelvis. Several biopsies were obtained that resulted in a diagnosis of metastatic carcinoma of the peritoneum.

The patient went rapidly downhill and died, and autopsy confirmed the finding of widespread abdominal carcinomatosis arising in the stomach and involving the wall of the rectum and both ovaries. The liver was normal except for infarction.

CASE 15. G. L. (B.M. U-385439), a 59-year-old woman, had an abdomen distended with gas and fluid. A mass in the right side of the abdomen was thought from x-ray examination to be liver but clinically was apparently not related to the liver.

At peritoneoscopy 9000 cc. of yellow, bloody fluid, which was under pressure, was aspirated. The liver did not appear to be abnormal. The peritoneal surfaces throughout were studded with numerous implants that appeared typical of carcinoma. Several biopsies were obtained that showed the diagnosis to be metastatic spindle-cell sarcoma, possibly of ovarian origin.

CASE 16. M. S. O'B. (B.M. U-189703), a 70-year-old man, gave a history of enlargement of the abdomen for 1½ years, with several taps yielding grossly bloody fluid. There was no marked weight loss. In spite of a negative history of alcoholism, the presumptive clinical diagnosis was cirrhosis of the liver.

At peritoneoscopy 750 cc. of thin, bloody fluid was aspirated. The liver appeared normal. Occupying the entire left side of the abdomen was a reddish-purple mass, partly covered with omentum and appearing extremely vascular and cystic. Diagnosis at the conclusion of peritoneoscopy was a possible large splenic or omental cyst.

Laparotomy revealed a large hemangiosarcoma, probably of retroperitoneal origin, which was successfully removed. X-ray treatment was then given. A year and a half later the patient was doing well; peritoneoscopy was repeated and there was no evidence of recurrence.

Although liver disease was not seriously considered in the following case, ascites was the presenting symptom and cirrhosis had to be excluded.

CASE 17. D. L. (B.M. U-299241), a 49-year-old woman, had distention of the abdomen of 4 weeks' duration with anorexia, easy fatigability and loss of weight.

At peritoneoscopy 5000 cc. of straw-colored fluid was aspirated. The liver appeared normal. Multiple cystic implants from 1 to 2 mm. in diameter were seen on the peritoneum throughout the abdomen and pelvis. The examiner's diagnosis was abdominal carcinomatosis, probably of ovarian origin, but the biopsy report was tuberculosis.

Jaundice

In this group jaundice was the outstanding sign. Ascites and hepatomegaly were frequently present. The differential diagnosis included carcinoma of the liver, toxic cirrhosis, biliary cirrhosis, bile stasis, hepatitis or some other infectious process.

CASE 18. M. S. (B.M. U-351346), a 77-year-old woman, entered the hospital because of jaundice of 1 month's duration and weakness of 6 months' duration. There had been some pain in the right back, dating from a fall 8 months before admission. There was no history of alcoholism. The liver was not definitely palpable, but there was dullness four fingerbreadths below the right costal margin. The spleen was not palpable. There was no ascites. No esophageal varices were demonstrable by x-ray. Because of these findings, cirrhosis of the liver of ordinary type was thought to be unlikely, and the presumptive diagnosis was carcinoma of the pancreas or biliary tract. A positive clinical diagnosis was impossible. A Graham test was negative. A brom-sulfalcin test showed 70 per cent dye retention.

Peritoneoscopy demonstrated a hobnail liver and a spleen enlarged to about twice the normal size. A biopsy of the liver resulted in a diagnosis of cirrhosis, unclassified.

In this jaundiced patient without a history of alcoholism, the most likely clinical diagnosis was thought to be malignancy, but peritoneoscopy revealed cirrhosis.

CASE 19. L. D. O'B. (B.M. U-396744), a 57-year-old woman, entered the hospital with a chief complaint of jaundice of 8 months' duration. Fourteen months prior to admission she had had a cholecystectomy at a local hospital. Six months later painless, progressive jaundice developed. She was operated on again at the same hospital and told that she had adhesions. The jaundice did not improve, and 3 months later she was again explored at the same hospital, with the same result. Although her appetite had been good, she had lost 60 pounds in 14 months.

Physical examination showed an intensively jaundiced patient with a hard, irregular mass involving the entire upper abdomen and extending into the right lower quadrant. Biliary cirrhosis following trauma to the common duct and carcinoma obstructing the biliary system was considered the most likely clinical diagnoses.

Peritoneoscopy showed the left lobe of the liver to be at the level of the umbilicus and the right lobe extended below the iliac crest. The surface throughout was smooth and grayish-black, with fine white mottlings and striations. No nodules were seen and there was nothing to suggest neoplasm in the liver. The spleen was not visible. A biopsy of the liver resulted in a diagnosis of biliary cirrhosis.

Exploratory laparotomy was later performed. The hepatic duct was found to end blindly and a vitallium tube was inserted to connect it with the duodenum.

In this severely jaundiced patient, peritoneoscopy excluded metastatic malignancy in the liver and established the diagnosis of biliary cirrhosis.

Doubtful Clinical Findings

CASE 20. A. M. (M.G.H. U-283167), a 35-year-old clerical worker, entered the hospital because of loss of appetite and easy fatigue. About 3 years before admission he had begun to have vague abdominal discomfort and epigastric fullness. Six months prior to admission he had been troubled with a slight cough productive of only a small amount of mucoid sputum.

Physical examination disclosed a large, firm mass in the left upper quadrant that was thought to be spleen. The liver was not felt. X-ray study of the chest demonstrated mottled, increased density in both upper lung fields, with a cavity in the right infraclavicular area. There was also some fine mottling in the left lower lung field. The films were interpreted as bilateral tuberculosis. One of the consultants believed that the x-ray picture, as well as the enlarged spleen might be explained on the basis of sarcoid.

Peritoneoscopy disclosed a spleen extending just below the level of the umbilicus, that was brown and smooth throughout except for three or four, grayish nodules of pinpoint size just above the splenic notch. The liver did not appear to be enlarged, but the anterior surface throughout both lobes was mottled with irregular, fine, gray striations. The capsule was extremely firm. A satisfactory biopsy, however, was obtained and the microscopic report was sarcoid.

In this case the presumptive clinical diagnosis was pulmonary tuberculosis and splenomegaly of undetermined cause. Peritoneoscopy showed that the whole process was due to sarcoid.

Primary Carcinoma of Liver

The following 5 cases of primary liver-cell carcinoma seem worth while reporting in some detail, as follows:

CASE 21. P. B. (M.G.H. U-150174), a 50-year-old man, entered the hospital complaining of upper-abdominal pain, epigastric distress, a weight loss of 25 pounds in 2 months and an upper-abdominal mass. The use of alcohol was denied.

Physical examination showed an irregular, hard, tender mass in the epigastrium, descending with respiration, which was probably liver. The spleen was not palpable. There was no jaundice or ascites. Esophageal varices were not demonstrable by x-ray. Since the mass in the epigastrium was so definitely tender and the patient was running a temperature up to 101°F., a diagnosis of liver abscess or malignancy was considered and peritoneoscopy was undertaken.

At that time the liver presented a slightly mottled, cobblestone appearance in one area, but there was nothing to suggest liver abscess or carcinoma. The biopsy was possible hemangioma.

Since the patient continued to run a temperature, exploratory laparotomy was performed, which revealed an abscess well within the substance of the liver and therefore not visible by peritoneoscopy. The abscess cavity was drained and another biopsy of the liver resulted in a diagnosis of carcinoma. Two months later the patient died at another hospital, and autopsy confirmed the diagnosis of primary carcinoma of the liver.

CASE 22. M. G. (M.G.H. U-382144), a 46-year-old man, entered the hospital complaining of girdling pain around the abdomen, abdominal swelling, anorexia, vomiting and diarrhea. He was a moderate user of alcohol.

Physical examination disclosed a markedly distended, tense abdomen, with a fluid wave and shifting dullness in both flanks. The liver edge was palpable 7 cm. below the costal margin border; it was apparently smooth and extended across the midline into the left upper quadrant. The spleen was not palpable. Slight jaundice was present. Esophageal varices were not demonstrable by x-ray.

At the time of peritoneoscopy, 3000 cc. of slightly cloudy, yellow fluid was aspirated. The liver throughout both lobes was definitely hobnailed and thickened. On the anterior surface of the right lobe there were several yellowish areas that suggested neoplasm but were not typical. A biopsy was obtained from one of these areas, and the tissue appeared necrotic rather than malignant. Another biopsy was obtained from an area that appeared cirrhotic. The pathological report was toxic cirrhosis and hepatoma.

CASE 23. S. F. (M.G.H. U-300235), a 51-year-old man, entered the hospital with a history of having vomited about a quart of bright-red blood. He had been a known diabetic patient for 12 years. He had always used a considerable amount of alcohol. The liver was palpable two fingerbreadths below the right costal margin. The spleen was not palpable, nor was there any ascites or jaundice. Esophageal varices were not demonstrable by x-ray.

At peritoneoscopy the liver throughout both lobes showed multiple yellowish nodules, varying from 2 to 10 cm. in diameter. In fact, the liver seemed to be at least one third to one half infiltrated with tissue that looked carcinomatous. The biopsy was toxic cirrhosis with possible neoplasia.

Seven months later, the patient died at another hospital and autopsy showed toxic cirrhosis and primary carcinoma of the liver, with metastases to the portal, mesenteric and pancreatic lymph nodes.

CASE 24. D. J. C. (H.H. U-40465), a 56-year-old man, entered the Huntington Memorial Hospital because of pain in the right upper quadrant, a severe chill, vomiting and loss of weight. He had been a heavy user of alcohol, especially before Prohibition, drinking "a dozen drinks a day."

Physical examination revealed a large mass filling the entire upper abdomen, having a tender, firm, smooth edge and moving with respiration, and questionable nodular areas in the epigastrium. The spleen was not palpable. There was slight jaundice and a small amount of abdominal fluid. No esophageal varices were demonstrable by x-ray.

At peritoneoscopy the liver throughout was studded with numerous whitish yellow, umbilicated lesions, varying from 2 to 5 cm. in diameter, many of them coalescing. The right lobe of the liver was almost completely replaced with tissue that had the appearance of carcinoma. About 2000 cc. of yellow fluid was aspirated. A biopsy of the liver resulted in a diagnosis of carcinoma, unclassified. About 2 weeks later

the patient died and autopsy revealed primary bile-duct carcinoma of the liver with metastases to the periportal and peripancreatic lymph nodes.

CASE 25. L. W. H. (P.D.H. U-8211), a 72-year-old man, entered the Pratt Diagnostic Hospital complaining of pain in the right upper quadrant, nausea and vomiting, weakness and loss of weight. He had been a moderate user of alcohol all his life.

Physical examination revealed at least three distinct masses within the abdomen. The first, taken to be liver, descended with respiration about four fingerbreadths below the right costal margin. The edge was sharp and irregular and definite tender nodules were palpated along its border. Below this was a round, extremely hard mass to the right of the midline, extending approximately to the level of the umbilicus. In the right flank a round, smooth, hard, slightly nodular mass was felt below the liver. The spleen was not palpable. There was no jaundice or ascites. Esophageal varices were not demonstrable by x-ray.

Peritoneoscopy disclosed a comparatively normal left lobe of the liver, but the edge of the right lobe was markedly rounded and contained a yellow nodule 3 to 4 cm. in diameter, consistent with carcinoma. Farther in the right flank, but continuous with the liver and more posteriorly, was a hard, gray, nodular mass, consistent with carcinoma invading the liver. There was another mass occupying the right upper quadrant below the liver, apparently distinct from the liver and covered entirely by omentum. A biopsy of the mass in the right flank resulted in a diagnosis of primary liver-cell tumor.

These 5 cases of proved hepatoma present certain features of interest. All the patients were men in middle or late life. All except one had used alcohol in moderate to large amounts. The only one who denied the use of alcohol was a native-born Armenian who may have been exposed to some unusual liver disease. All except one complained of upper abdominal pain, usually in the right upper quadrant or epigastrium. Loss of weight and vomiting were noted in 3 cases.

In all cases physical examination showed an upper abdominal mass, usually of considerable size and frequently thought to be somewhat nodular. The spleen was not palpable in any case, nor were esophageal varices ever demonstrable by x-ray. Jaundice and ascites were present in 2 cases.

The biopsies obtained at peritoneoscopy were positive in 2 cases for hepatoma, in 1 case for carcinoma (unclassified), and in 1 for toxic cirrhosis with possible neoplasia. There was some difference of opinion among the pathologists in the fourth case, and it was thought that if carcinoma were present it was primary hepatoma. In the fifth case, the neoplastic areas were not demonstrable by peritoneoscopy, owing to adhesions and also to the fact that the neoplasm was within the substance of the liver.

Heretofore it has always been impossible to make a positive clinical diagnosis of primary carcinoma of the liver, but with the aid of the peritoneoscope a positive diagnosis is now possible.

DISCUSSION

Since the division of these cases into groups is obviously arbitrary, it may be as well to discuss all of them together. It is evident that peritoneoscopy

is a procedure that is of great importance and that by this method alone many doubtful clinical diagnoses can be positively established and some others entirely changed. Peritoneoscopy may be safely performed in many patients on whom one would hesitate to do a laparotomy or where a laparotomy would be too formidable a procedure for the information obtainable.

Is metastatic cancer present in the liver? Its presence or absence may change the treatment entirely. Given a large nodular mass in the epigastrium it may be assumed clinically to be cancer in the liver, but peritoneoscopy may show that the mass does not involve the liver; it may be a large carcinoma of the stomach that can be successfully resected. Conversely, a nonpalpable liver may contain metastatic cancer demonstrable by peritoneoscopy and a laparotomy may thus be avoided.

The fact that a liver is large is interesting and important, but what does it mean? Liver-function studies may show good or bad function, but still one does not know the diagnosis until a biopsy is performed. Many times I have been surprised to find cirrhosis when I suspected cancer, and vice versa; and at other times cancer is superimposed on cirrhosis. Occasionally, sarcoma is found instead of cirrhosis. Sometimes when liver disease has been suspected, peritoneoscopy has revealed a large, normal liver, ovarian carcinomatosis, hemangiosarcoma or tuberculous peritonitis. Moreover, by getting liver biopsies in cirrhosis before and after treatment, it is possible to watch the progression

or regression of the process, and thus evaluate the therapeutic procedures. The differential diagnosis of patients with ascites or jaundice, or both, is often difficult, but by direct endoscopic inspection the problem frequently is easily solved. A rare diagnosis, such as sarcoid of the liver, may occasionally be made by peritoneoscopy. Primary liver-cell carcinoma can be positively diagnosed by peritoneoscopic biopsy.

CONCLUSIONS

Peritoneoscopy is an important and well-established method of examining the peritoneal cavity that is especially applicable to the differential diagnosis of liver disease. With biopsy, a suspected diagnosis is made positive.

In a series of peritoneoscopies in 435 patients, the examination was undertaken primarily to study the liver in over two thirds of the cases. One hundred and seventy patients were found to have metastatic carcinoma, 73 had cirrhosis, and the remainder had various diseases, including hepatoma, sarcoma, lymphoma, lymphangioma, Banti's disease, cholangitis, polycystic liver, echinococcal cyst and sarcoid.

DICUMAROL THERAPY IN THROMBOTIC EMERGENCIES*

JAMES A. EVANS, M.D.†

BOSTON

SINCE August, 1941, it has been the policy at the Lahey Clinic to treat thrombotic emergencies by one or more of the following three relatively new methods: paravertebral procaine sympathetic block,¹ venous section and ligation,² and anticoagulant therapy with Dicumarol, with or without heparin.³ Procaine sympathetic block is reserved for patients with thrombophlebitis (phlegmasia alba dolens) in whom swelling exists, in order to abolish constrictor reflexes, promote arteriolar pulsation, enhance oxygenation, restore normal capillary pressure, and thus reduce edema. Sympathetic block probably has no influence on the prevention of pulmonary embolism.

Because of the probable efficacy of anticoagulation therapy in the prevention of postoperative embolism, venous section and ligation are reserved for patients with phlebothrombosis who are over fifty years of age and who have had a warning benign embolism. This rule is not absolute, however, even in these cases, and the procedure has been resorted to only four times since October, 1941. So far there has been no fatality and only one recognizable recurrent benign pulmonary embolism among 46 patients with postoperative venous thromboses treated by anticoagulation therapy, all of whom were candidates, in varying degree, for pulmonary embolism. The phrase "in varying degree" is used advisedly because only 23 of these patients fell into the group with postoperative benign embolism, who are notoriously likely to develop subsequent benign or fatal emboli. We do not hesitate to employ venous section and ligation in patients with a history of multiple pulmonary emboli, postoperative or otherwise, but we advise a prolonged course of anticoagulation therapy after ligation when there is a likelihood of continuing active phlebitis and formation of venous thrombi. This is considered necessary because at autopsy venous thrombosis has been seen to extend above the point of section and ligation and to constitute the source of further pulmonary emboli, although severance of the vein was at a point above the level of the clot.

A rational use of these three methods, either singly or combined, was the subject of another paper.⁴

Anticoagulant therapy by heparin alone is expensive for the patient and tedious and laborious for the professional staff, but with the advent of Dicumarol, which can be given by mouth, there is available a cheap and easy preventive of intravascular clotting. However, heparin is now being given the first two

to five days to cover the immediate emergency period before Dicumarol has caused a fall in the prothrombin percentage.

CLINICAL USE OF DICUMAROL

The advantages of anticoagulation therapy with Dicumarol were discussed in statistical studies by Allen, Barker and Waugh.⁵ The experience at the Lahey Clinic, as outlined in this paper, corroborates their conclusions. In addition, I wish to point out the danger of hemorrhage and even death in the use of this potent hemorrhagic agent.

The isolation of Dicumarol (3,3'-methylenebis, 4-hydroxycoumarin), the active principle of spoiled sweet clover causing hemorrhagic disease of cattle, by Link and his associates⁶⁻⁹ at the Wisconsin Agricultural Experiment Station at the University of Wisconsin and the pioneer clinical work by Meyer and his associates^{10,11} and of Butt, Allen and Bollman¹² are examples of excellent pharmaceutical and clinical research. The scientific curiosity of a veterinarian, Roderick,¹³ prompted the development of this new drug after Quick¹⁴ proved that its action on the clotting mechanism is due to the lowering of the prothrombin content of the blood. Whether this action is due to the inhibition of the formation of prothrombin in the liver or in the blood stream is unknown. Butt, Allen, Bollman and Preston^{12, 15} have shown that intravascular clotting is delayed when the prothrombin time is prolonged by Dicumarol.

I have found, as have other investigators,^{5, 10-12, 15, 16, 17, 18} that Dicumarol has no consistent effect on the platelets, hemoglobin, red-cell count, white-cell count, capillary fragility, clot retraction, serum calcium or fibrinogen. The clotting time was prolonged only when the prothrombin time was reduced to low levels, usually around 40 per cent of normal.

REGULATION OF DOSAGE

After trying various doses of Dicumarol, an initial dose of 300 mg. for a patient below 120 pounds and 400 mg. for one over 120 pounds was adopted. A daily maintenance dose of 100 to 300 mg. was administered, depending on the rapidity of the fall of the prothrombin time. The average total amount required to maintain the prothrombin time below 75 per cent† was 1200 mg. in eight days. When the

*The prothrombin time is expressed in percentage of normal because the rate of clotting of the blood is directly proportional to the amount of prothrombin present, as described by Quick.¹⁴

†The thromboplastin proved to be too active for use in the laboratory, so the thromboplastin was diluted with saline solution.

*From the Department of Internal Medicine, Lahey Clinic. Read in part before the Boston Surgical Society, April 24, 1943.

†Member, Department of Internal Medicine, Lahey Clinic.

prothrombin time fell below 60 per cent or fell precipitously, the drug was discontinued. These doses of Dicumarol were given regardless of whether heparin was administered simultaneously. Heparin administration in itself may cause a fall of the prothrombin percentage to around 75 per cent of normal and does not necessitate stopping the Dicumarol. The administration of heparin is guided by the clotting time, Dicumarol by the prothrombin percentage.

One of the greatest difficulties in Dicumarol therapy is the determination of the amount of Dicumarol necessary to obtain the desired effect on prothrombin time. The maximum dose in this series was 3300 mg. in fourteen days, which was followed by reduction of the prothrombin time from 89 to 35 per cent. The minimum dose was 576 mg. in two days, reducing the prothrombin time from 78 to 27 per cent. The prothrombin time may continue to drop as long as five days after the drug is discontinued. Bleeding may occur with the prothrombin percentage below 40. The latent period of Dicumarol varied from one to six days. In combined heparin and Dicumarol therapy, therefore, it may be necessary to administer heparin longer than the average two-day period. Of 56 patients receiving Dicumarol, 5 who had adequate doses gave no response. Two of these were also heparin resistant. Others have noted this phenomenon in postoperative venous thrombosis, which is sometimes accompanied by a rise in platelet count and prothrombin time, and may indicate true hyperprothrombinemia. One of the patients exhibited irreversible shock and bloody pulmonary edema in spite of adequate replacement of blood loss by transfusion.

PRECAUTIONS TO BE OBSERVED

The following precautions should be observed: Dicumarol should not be given to patients with hepatic damage, especially if reduction in prothrombin percentage has already occurred. Its use is contraindicated in any case of hemorrhagic diathesis except in those cases in which it is considered certain that splenectomy will cure the condition. The morning prothrombin time should be determined before the daily afternoon dose of Dicumarol is given.

The typical course of a case under combined Dicumarol therapy and heparin is shown in Figure 1. The source of the pulmonary embolism was thought to be a pelvic phlebothrombosis following surgical resection of a carcinoma of the right ovary with side-to-side anastomosis around a carcinoma of the sigmoid. A thirty-six-hour latent period in the action of Dicumarol was evident. When heparin was discontinued, the Dicumarol effect was maintained for at least seven days. The patient was allowed to get out of bed without incident nine days after the occurrence of pulmonary embolism.

If the patient's surgical condition permits, he may sit up when the prothrombin percentage is below 70. Of this series of venous thrombotic patients, 68 per cent were out of bed without untoward incident within two weeks of recognition of the original vascular accident.

Table 1 gives the varieties of thrombotic emer-

TABLE 1. Diagnoses in 56 Cases Treated with Dicumarol Alone or Combined with Heparin.

DIAGNOSIS	No. of Cases

gencies found in the patients receiving Dicumarol either alone or combined with heparin in the nineteen-month period (August, 1941, to April, 1943).

RESULTS OF DICUMAROL THERAPY

During the nineteen-month period, 46 patients with venous thrombosis or a history of venous thrombosis were treated with Dicumarol (Table 2). Thirty

TABLE 2. Data in 46 Cases of Postoperative Venous Thrombosis.

REASON FOR ANTI-COAGULANT THERAPY	NUMBER OF CASES	SUBSEQUENT THROMBOSIS	SUBSEQUENT EMBOLISM	SUBSEQUENT FATAL EMBOLISM

Venous thrombosis or embolism complicating previous operation	6	0	1	0
Totals	46	0	2	0

*Thirteen of these patients had thrombophlebitis; the other 4 had phlebothrombosis.

of these patients also received heparin. Six of them also had paravertebral sympathetic procaine block. None had venous division and ligation.

I have divided these cases, as did Allen, Barker and Waugh⁵ at the Mayo Clinic, into three groups: postoperative pulmonary embolism or infarction, postoperative venous thrombosis, and venous thrombosis or embolism complicating previous operation. These authors compared the expected number of emboli in untreated patients with the actual number that occurred under Dicumarol therapy, their expectancy figures being those prepared by Barker and his associates.¹⁹ It is doubtful whether such

expectancy figures can be applied with accuracy to patients in another clinic with different hospital and surgical routines and under different climatic conditions. Since such expectancy figures from the Lahey Clinic have not been compiled on account of

embolism occurred. In none of the 46 patients with venous thrombosis did additional foci of thrombophlebitis or phlebothrombosis become evident once treatment was begun. Of the 40 patients in whom venous thrombosis occurred after operation,

FIGURE 1. Course of a Case under Combined Dicumarol and Heparin Therapy.

the pressure of wartime work, all that can be reported is that only 1 subsequent benign and no subsequent fatal embolism were encountered in 23 patients with postoperative pulmonary embolism treated with heparin combined with Dicumarol. The embolism occurred when the prothrombin time was reduced to 55 per cent.

In 17 cases of postoperative venous thrombosis uncomplicated by embolism at the time of beginning anticoagulation therapy, no pulmonary embolism occurred. Since phlegmasia alba dolens is rarely a cause of pulmonary embolism, this group has been subdivided into 13 cases of thrombophlebitis and 4 of phlebothrombosis. All observers in this field realize that other silent foci of phlebothrombosis often occur in thrombophlebitis and give rise to pulmonary embolism, well justifying the protection of such patients. Also, my experience has shown that anticoagulation therapy greatly shortens the morbidity period from phlegmasia alba dolens.

In 6 patients with a history of thrombophlebitis or embolism following a previous operation, no

with or without pulmonary embolism, 9 were out of bed one week or less after the initial vascular accident was recognized, and 27 within two weeks.

Among the 46 patients with venous thrombosis no fatal pulmonary embolism occurred.

COMPLICATIONS

Of the 4 deaths occurring during Dicumarol therapy (Table 3), 2 can be attributed to hemor-

rhage, the result of lowered prothrombin content of the blood.

The first death occurred following a second-stage sympathectomy for chronic deep femoral thrombophlebitis. Venograms before and after spinal anesthesia had demonstrated a spastic element. Following the first-stage sympathectomy, Dicumarol was given successfully. The prothrombin time was allowed to return to normal before the second stage was done, after which Dicumarol was again administered. The second daily dose of the second course of Dicumarol was given before that morning's prothrombin time was determined. By the third morning the prothrombin time had dropped to 37 per cent, after 688 mg. of Dicumarol had been given in two days. The patient had signs of hemorrhage and shock, and six transfusions failed to save her life. Autopsy showed hemorrhage into the abdominal wall, retroperitoneal tissues and wound and bloody pulmonary edema.

The second death due to hemorrhage occurred in a patient with a dissecting aneurysm of the aorta, which was proved at autopsy but was mistaken during life for a postoperative pulmonary embolism. Three daily doses of Dicumarol—400, 200 and 100 mg., respectively—were given, the prothrombin time falling precipitously from 100 to 54 per cent in three days. By the fourth day, without further Dicumarol, the prothrombin time fell to 33 per cent, where it remained for the next five days, when the patient was allowed to sit up. Six days after the last dose of Dicumarol, the prothrombin time suddenly fell to 11 per cent. The only sign of hemorrhage was moderately bloody urine whose source was a transurethral resection that had been performed three weeks before. Because of the low prothrombin level, a transfusion was given, but death occurred suddenly three hours later, with blood exuding from the patient's mouth and nose. Autopsy showed petechial hemorrhages into the pericardium, a gastric mucosa oozing blood, a stomach full of blood and regurgitation of blood into the esophagus. No communication between the dissecting aneurysm and the esophagus or stomach could be found. This patient would undoubtedly have died of the dissecting aneurysm, but perhaps under other circumstances might have been saved by repeated transfusions.

The third death was due to a perforated gall bladder, and the fourth to gangrene of both legs from saddle embolism.

Table 3 gives a summary of the hemorrhagic accidents in the total series of 56 patients. Transfusion was necessary in 3 cases. There were 2 deaths directly ascribable to Dicumarol (4 per cent) and 8 cases with hemorrhage (14 per cent).

SUMMARY AND CONCLUSIONS

Fifty-six patients with thrombotic emergencies were treated by Dicumarol or Dicumarol combined

with heparin as anticoagulants, between August 1941, and April, 1943. Two deaths occurred (4 per cent), 1 of which can be attributed unequivocally to Dicumarol poisoning and hemorrhage. Hemorrhagic phenomena were evident in 8 cases (14 per cent). These complications emphasize the dangers and disadvantages of Dicumarol therapy, but the obvious advantages to date appear to outweigh the dangers of this preventive method if adequate laboratory facilities are available and proper precautions are observed.

The principal precaution to be observed is the determination of the morning prothrombin time before ordering the daily maintenance dose of Dicumarol.

The combined use of heparin and Dicumarol is considered safe only if the doses of heparin are controlled by twice-daily determinations of the coagulation time of the blood, and the doses of Dicumarol by daily determinations of the prothrombin time.

One benign and no fatal pulmonary embolism occurred in a series of 46 cases of venous thrombosis treated by the anticoagulant Dicumarol, alone or combined with heparin.

This series of 46 cases of thrombophlebitis is not large enough to draw the conclusion that venous ligation is an unnecessary procedure. If a patient over fifty and has had a warning benign pulmonary embolism, therefore, venous ligation is still indicated. If statistical proof can be accumulated from other workers in this field, venous ligation may prove unnecessary except in rare cases of recurrent embolism occurring in spite of anticoagulation therapy.

ABSCESS OF THE SPLEEN*

IRVING NORMAN WOLFSON, M.D.†

NEW YORK CITY

ABSCESS of the spleen has attracted little attention in the American literature. Although excellent reviews and case reports have been published by Elting,¹ Inlow,² Billings,³ and Walker⁴ and recently by Lemmon and Paschal,⁵ the European literature on the subject is much more extensive. This is unfortunate, for, although splenic abscess is not of frequent occurrence, its diagnosis is not difficult when kept in mind. Furthermore, the correct therapeutic approach greatly reduces an extremely high mortality rate (80 to 100 per cent^{2, 6}).^{2, 3} It would be most unfortunate, therefore, if the diagnosis were missed simply because the possibility had not been considered. Splenic abscess occurred in 0.4 per cent of autopsies at the Boston City Hospital, according to Walker,⁴ and Billings³ reported 24 cases in 3600 autopsies, an incidence of 0.7 per cent.

The classification of splenic abscesses has been simplified since Kuttner⁷ outlined seven varieties in his classic paper on the subject. Three major modes of pathogenesis are now generally recognized.

Traumatic abscesses constitute an estimated 15 per cent of all splenic abscesses. Clinically they result from trauma to the organ, with a resultant perisplenic hematoma. Under such conditions, the hematoma forms a point of lessened resistance, and is subject to suppuration whenever there occurs a bacteremia resulting from major or minor infective processes. Experimentally, splenic abscesses have been produced by Caldarera,⁸ who rendered animals' spleens susceptible by traumatizing them and injected *Staphylococcus aureus*. Kuttner⁷ similarly produced abscesses of the spleen. In 1927, Inlow reviewed 23 cases of traumatic abscess and discussed one of his own. He found that conservative treatment of these cases resulted in a mortality of 100 per cent, whereas with surgical intervention this figure was reduced to 38 per cent.

Abscess of the spleen occasionally results from extension of a neighboring pathologic process. Thus, infected colonic or gastric neoplasms may invade the spleen, or left subphrenic collections may erode into it so that the organ forms the floor of the abscess cavity. In a case seen at the Mount Sinai Hospital,

a large abscess was found in a spleen invaded by lymphosarcomatous tissue. Most such cases are of only academic interest, since the patient is usually suffering from a serious condition to which the splenic abscess is secondary and drainage of the abscess would be of no therapeutic benefit.

The most important group of splenic abscesses are those resulting from metastatic spread of infection elsewhere. Thus, furunculosis, erysipelas, otitis media, and femoral thrombophlebitis, as well as appendicitis and salpingitis, have preceded development of abscess of the spleen. It is important to divide this group into those cases in which the infection spreads along venous channels, and those in which the infection reaches the spleen through the splenic artery. Cases in the first group, which includes the case presented below, usually result from intra-abdominal suppuration. Cases that come to autopsy usually show pyelophlebitis and thrombophlebitis of the splenic vein. Thus, Fauntleroy⁹ reported a case following acute appendicitis in which autopsy revealed three splenic abscesses with thrombosis of the splenic vein and with numerous small necrotic areas in the liver. Cooke¹⁰ found a large and septic spleen with purulent thrombophlebitis of the mesenteric and splenic veins resulting from a perforated colonic diverticulum. Such cases tend to have a serious prognosis because of the associated venous lesions.

The large number of cases resulting from suppuration elsewhere are probably due to spread of infection by way of the splenic artery. In this group must belong Walker's⁴ case, with streptococcal sepsis resulting from thrombosis of the lateral sinus secondary to mastoiditis; Billings's³ case, in which *Staph. aureus* was cultured from a recently incised carbuncle of the neck as well as from the splenic abscess; Cutler's¹¹ case, which was preceded by otitis media; Eliason's¹² case, in which a staphylococcal sepsis and splenic abscess followed a peritonitis abscess, and the case of Lemmon and Paschal,⁵ in which a splenic abscess was preceded by thrombophlebitis of the femoral vein. In these cases, it is apparent that the infecting material must have traversed the lesser circulation and escaped the pulmonary network in order to reach the spleen. The only alternative pathway is through a congenital

*From the Medical Service of Dr. George Bachr and the Surgical Service of Dr. Harold Neuboh, Mount Sinai Hospital, New York City.
 †Intern, Mount Sinai Hospital.

cardiac defect. In most cases, however, no cardiac murmurs indicative of such a lesion are described.

Special mention should be made of the group of cases described by Rabin and Moolten.¹³ These observers reported 5 cases of lung abscess from which splenic abscess developed—presumably by way of the splenic artery. In each case, infection of a branch of the splenic vein occurred at the site of the abscess and eventually resulted in fatal pyelphlebitis.

Metastatic splenic abscess may develop clinical manifestations from one day to several months after the appearance of the primary source. The onset is often heralded by sudden severe pain in the left hypochondrium, although the pain may also be of gradual onset. On the other hand, when a large abscess is buried in the middle of the spleen, there may be no pain referred to the splenic region, as in Fauntleroy's⁹ case. It is usually stated that abscesses of the upper pole of the spleen give rise to pleuritic pain, with inspiratory increase of the pain and occasional radiation to the left shoulder, whereas abscesses of the lower pole give rise to peritoneal signs. In general, this is true, but it should be noted that in May's¹⁴ case a superior pole abscess ruptured into the peritoneal cavity. Accompanying the pain are the general symptoms of severe infection—temperature, usually spiking, chills and leukocytosis. The temperature generally reaches 103°F. or more, but in Lemmon and Paschal's⁵ case it remained below 100 before drainage of the abscess. Similarly, the white count may reach 20,000 to 30,000 but in several cases has been below 10,000. It is apparent, therefore, that splenic abscess should be suspected in any patient with pain in the left upper quadrant of the abdomen, especially if an adequate previous focus of infection is found or if there are any symptoms or signs of sepsis.

Physical examination usually discloses tenderness and spasticity in the left upper quadrant, and careful observation may reveal edema of the soft parts overlying the spleen and even a tense, glistening skin. The spleen is almost always enlarged, and is usually felt clinically. There may be signs of fluid in the left pleural cavity, and radiologic examination may disclose this, with or without elevation of the left leaf of the diaphragm.

Splenic puncture as a diagnostic measure has been both supported and condemned. The procedure is obviously not without danger. In doubtful cases, however, it is useful. The safest policy is to restrict its use to such cases and to have the puncture performed in the operating room, with all preparations made for splenotomy or splenectomy. If pus is aspirated, the needle should be left in place until the spleen is exposed. In this way, the danger of producing empyema by introducing pus along the track of the needle is obviated.

If untreated, splenic abscesses run a severe septic course. A few become chronic, with sterile pus, and

produce few symptoms. The overwhelming majority, however, rapidly go on to a fatal termination if surgical intervention is not instituted. The procedure employed may be splenectomy or splenotomy. Splenotomy is usually preferred unless the organ is easily mobilizable and free of adhesions, when splenectomy may be indicated. Of 55 cases gathered by Billings,³ splenotomies were performed in 51, with 7 deaths, and splenectomies in 4, with 3 deaths. Splenotomy may be performed through a transpleural, transperitoneal or retroperitoneal approach. This varies with the site of the abscess, as well as with the preference of the surgeon.

In those cases in which suppuration is localized in the spleen, surgical intervention produces a cure in the majority. Operation is contraindicated in cases of splenic abscess resulting from subacute bacterial endocarditis, in which the prognosis is necessarily the grave one of the underlying disease. Similarly, surgery cannot offer much hope when the abscess is secondary to extensive pyemia with multiple suppuration elsewhere, for in such cases the splenic lesion is an incidental and unimportant finding. When the splenic abscess is the result of, or causes, suppurative splenic and portal thrombophlebitis, the prognosis is usually grave, but surgery offers the patient a slight chance, especially if splenectomy with ligation of the purulent vein can be performed. Such a case, with an unsuccessful result, is reported below.

Of 30 cases of splenic abscess described by Walker¹ from autopsy material, 22 had abscesses involving other organs, leaving only 8 that could be benefited by surgery. Since this series included only cases seen at autopsy, patients diagnosed clinically as splenic abscess have a higher percentage of operability.

CASE REPORT

A 27-year-old woman bookkeeper (501064), was admitted to the Mount Sinai Hospital on January 30, 1943. Six weeks before admission, she had an appendectomy with drainage at another hospital, because of a 2 weeks' illness characterized by abdominal pain, fever and pharyngitis. The removed appendix was reported as showing periappendicitis. Three weeks postoperatively, the patient was discharged well, but on the same day she developed shaking chills, fever up to 105°F. and sweats. One week after discharge she returned to the hospital, where she continued to have high fever and sweats, without localizing symptoms. After 2 weeks she was transferred to the Mount Sinai Hospital.

Physical examination on admission revealed an acutely ill woman. The temperature was 105.0°F., the pulse 130, the respirations 30, and the blood pressure 110/58. The eyes, ears, nose and throat were normal. Examination of the lungs disclosed an impaired percussion note and diminished breath sounds at the left base. There were no rales. The heart was not enlarged. There was a short systolic murmur at the apex, and embryocardiac rhythm was noted. In the right lower quadrant of the abdomen was a wound draining a minimal amount of mucopurulent material. The liver was barely palpable, and under the left costal cage a definite tender mass was felt. Both costovertebral angles were tender, and there was a suggestion of a bulge on the left. The white-cell count on admission was 30,000, with 95 per cent neutrophils. The urine showed a trace of albumin and a few granular and cellular casts. A blood culture taken on admission was later re-

ported as positive for beta-hemolytic streptococcus. X-ray examination of the chest showed a small amount of fluid in the lower portion of the left pleural cavity. There was no elevation of the diaphragm.

The day after admission, the left side of the chest was tapped. The 10th interspace was entered at one third of the distance from the posterior axillary line to the spine. Superficially, after penetration for a short distance, thin sanguinous fluid was obtained. The needle was inserted deeper, and at a depth of 5 cm. pure pus was obtained, from which beta-hemolytic streptococci were grown. The patient was therefore removed to the operating room.

The report of the surgeon (Dr. Harold Neuho) follows:

Aspiration at the level of the 10th interspace revealed pus. The needle was left in place and the 11th interspace was aspirated. Here sanguinous fluid was obtained. A preoperative diagnosis of splenic abscess with rupture of the spleen was made.

Accordingly, the 11th rib was liberally excised. The pleural cavity, which was free of fluid but potentially infected by aspiration, was traversed and an upward bulge of the diaphragm toward the midline was noted. General anesthesia was administered, local anesthesia having been employed up to this point. The diaphragm was sutured to the margins of the thoracic wound and was then incised, its edges being pulled up to the surface and sutured over the first layer in order to shut off completely the free pleura. This was achieved down to the posterior part of the wound, at which place a tube was inserted for drainage of the potentially infected pleura. The collection of pus was opened up and was found to be partly within and partly outside of the spleen. The latter was found to be split in two. There was then evacuated a considerable collection of old fluid blood from beneath the diaphragm, situated more medially than the collection of pus. The abscess cavity was packed.

The subphrenic space itself was lightly sealed off by adhesions between the spleen and abscess wall on one side and the undersurface of the diaphragm on the other side. Thus there was no true subphrenic abscess.

Postoperatively, the patient showed no improvement. The temperature continued to range from 102.4 to 106°F. despite blood transfusions and the administration of sulfathiazole. On the 2nd day the patient became confused and disoriented. She continued to run a septic downhill course and died 3 days postoperatively.

Autopsy (12407). The relevant findings at the autopsy performed by Dr. L. Strauss, were reported as follows:

The spleen is enlarged, weighing 380 gm. At its upper pole there are two large irregular defects, one on the anterior surface, the other on the posterior surface underneath the adherent diaphragm. In the vicinity of these defects, the capsule shows irregular, yellowish-gray discoloration, over the remainder of the organ it is smooth and of normal color — purplish gray. On section, a huge, multiloculated abscess is found, involving about half the spleen. It is lined by ragged, necrotic tissue and filled with blood clots. The lower half of the spleen is soft and shows abundant bright-red pulp and distinct follicles. The splenic artery shows no change.

From the portal spaces thick, yellow pus exudes in many areas throughout the liver. The portal vein is thickened, and its lumen contains adherent membranous

fibrinous material and frank pus. Pus also wells up from many of its intrahepatic branches. At the point of junction of the superior mesenteric and splenic veins and in the splenic vein, slightly adherent fibrinous thrombi are encountered.

The right tube is thickened and hyperemic, and its fibrinated end is closed. In the cul-de-sac, irregular, raised yellow patches are seen on the serosa.

The small intestine does not show noteworthy changes except for the lower part of the ileum, where numerous fibrous bands are found connecting various loops. There is grayish discoloration of the serosa, which is irregularly thickened over the mesentery. Small yellow patches are found on the mesentery near the insertion of the bowel. The branches of the superior mesenteric veins are not involved by the thrombotic process. The cecum is adherent to the ileum; the appendix has been removed.

Anatomical diagnoses: purulent thrombophlebitis of the portal and splenic veins; left subphrenic and splenic abscess; chronic mesenteritis and localized peritonitis of the ileocecal region; chronic right salpingitis; and chronic peritonitis of the cul-de-sac.

SUMMARY

Splenic abscess is an infrequent but not rare condition. Its diagnosis is not difficult when it is kept in mind. A patient who develops symptoms and signs of a lesion in the left upper abdomen and who has a recent history of even minor suppuration elsewhere should be explored and splenotomy or splenectomy performed.

A case of splenic abscess is reported that had its origin in a diffuse inflammatory process of the pelvic peritoneum. The abscess was accompanied by a pyelephlebitis and a thrombophlebitis of the splenic vein that led to a fatal outcome, despite surgical intervention.

MEDICAL PROGRESS

SYPHILIS (Concluded)

G. MARSHALL CRAWFORD, M.D.*

BOSTON

CLINICAL PROBLEMS

Syphilis in Blood Donors

A study of the method of handling blood donors found to have a positive or doubtful reaction for syphilis has been made by Frye, Keller and Kampmeier.³⁶ A geographically representative group of 603 hospitals replied to a questionnaire sent out by these authors. Of these institutions, 6.5 per cent were not testing blood donors for syphilis, small hospitals predominating. Among the hospitals testing donors, 12.5 per cent had no definite system for notifying these donors when they were found to have a positive or doubtful reaction for syphilis. Of all the hospitals, 16.2 per cent either did not examine donors for syphilis or did not notify them when the serologic test was positive. These findings indicate the need in many hospitals of more definite plans whereby the donors will be given blood tests and will be notified concerning the results. The present situation seems most deplorable. It could be construed as a grave reflection on hospital authorities, especially in view of the intense campaign to control syphilis. Financial considerations are, of course, sometimes strong deterrents, but surely it should not be too much to expect even the smallest institutions to send blood specimens to their state laboratories. One could even conceive of a malpractice suit arising on the basis of negligence should transfusion syphilis occur, or should an untested donor develop crippling lesions within a reasonable period of time.

False-Positive Serologic Reactions following Smallpox Vaccination

A reference to the phenomenon of false-positive serologic reactions following smallpox vaccination was given in a previous progress report on syphilis in this journal.³⁷ It seems of sufficient importance to warrant mentioning confirmatory data. Lubitz³⁸ observed 13 of 100 patients who exhibited positive serologic reactions for syphilis following a primary take with smallpox vaccination. All these cases had been serologically negative within a few months previously. Infectious mononucleosis was ruled out by a heterophile antibody test in the serums from 10 cases. The Kahn verification test gave no conclusive

evidence that these were false-positive reactions. Twelve of the patients could be followed, and their serums gradually became negative. The author states that a positive serologic test may be found as late as the fifth month following vaccination.

Syphilitic Spondylitis

A report by Freedman and Meschan³⁹, seems of interest because syphilitic spondylitis, although not common, can be so easily confused with other conditions. The authors point out the difference between syphilitic spondylitis and Charcot's spine. There seems to be a marked predilection for involvement of the cervical vertebrae in syphilitic spondylitis, possibly because of more likely exposure to slight trauma and pressure. The condition may occur in congenital syphilis or during the second or third stage of acquired syphilis. There is localized pain, which may be more marked at night, stiffness and tenderness to palpation. The normal lordosis of the spinal column is offset. The head is held stiff and motion is avoided. Coexisting osseous lesions are common. To substantiate a diagnosis, active syphilis should be demonstrable and there should be rapid improvement under antisypilitic treatment. Tuberculosis of the spine may be confusing, and the two conditions may coexist. In the majority of cases the vertebrae become surrounded by more or less spur formation, imitating roentgenographically the appearance of a nonsyphilitic inflammatory spondylitis.

Neurosyphilis

The interpretation of spinal-fluid reports is often a source of concern to general practitioners, and a discussion of this subject by Rose⁴⁰ is instructive. The point is made that cerebrospinal-fluid examination is essential in establishing the diagnosis of neurosyphilis, as well as in establishing the base line for future guidance. The initial findings do not, of course, indicate the prognosis. The several spinal-fluid findings in the various types of neurosyphilis are reviewed, and the significance of component parts of the reports is explained. Rose believes that the reversal of a positive spinal-fluid reaction to negative with a year or less of treatment is strong evidence against a diagnosis of general paresis, irrespective of clinical symptoms. Repeated examinations of the spinal fluid are considered essential for guidance and adequate therapy. This author states that the cell

*Instructor in dermatology, Harvard Medical School; assistant dermatologist, Massachusetts General Hospital.

count and the level of total protein are of much greater importance regarding prognosis and therapy than is the Wassermann test or the gold-sol curve. It is postulated that a spinal fluid that remains strongly positive in all elements for a year or more after the institution of therapy shows that some other form of treatment should be considered. Most syphilotherapists are somewhat less conservative in this respect. In asymptomatic neurosyphilis six months of routine therapy with trivalent arsenic and bismuth is usually considered sufficient trial, complementary methods of therapy being instituted at the end of this time if the spinal fluid is not improved. In the various forms of symptomatic neurosyphilis it may be necessary to use more drastic forms of therapy within a few weeks or months if symptomatic progression is not retarded.

In view of widespread, and in some instances alarming, epidemics of anterior poliomyelitis within the last year, an article by Barker⁴¹ seems timely. A case exhibiting an acute syphilitic anterior poliomyelopathic syndrome was reported. Although this picture is seldom seen, syphilis has been reported in a small number of cases as responsible for the origin of the syndrome of anterior poliomyelitis. Barker's patient was thirty-nine years old, and a diagnosis of acute anterior poliomyelitis was made on admission to the hospital. Laboratory tests showed strongly positive Wassermann reactions of the blood and cerebrospinal fluid. The case was observed in March, which is an untimely month for acute anterior poliomyelitis. There were absence of pain and a peculiar distribution of paralysis, inability to swallow existing in conjunction with weakness of both legs. Five days after admission the patient became unable to void urine. Under intensive anti-syphilitic therapy with bismuth, arsenic and potassium iodide, improvement was rapid, and within two months the symptoms had almost disappeared. The lesson in this situation seems obvious. Intensive anti-syphilitic treatment under such circumstances may prevent changes in the spinal cord that are not already irreparable from becoming so, by the restitution of better circulatory conditions in the cord through regression of the vascular syphilitic progress.

Trauma has long been implicated as a contributory factor in the development of many lesions of syphilis. Ample evidence in favor of this belief has been found from time to time. Merritt and Solomon⁴² present further substantiation of the role of trauma in the production or exaggeration of symptoms in the various types of neurosyphilis. It is stated that a causal relation between head trauma and the development of parietic symptoms may be established within six weeks of the trauma and perhaps as long as two to three years after it. The relation of trauma to syphilitic arthropathies affords less opportunity for divergence. It is generally accepted today that Charcot's joints develop as a result of lessened sensitivity in the joints that allows repeated minor

trauma to occur without protection by the muscles or the tendons. There is less evidence of the effect of injury in other types of neurosyphilis. The one proved fact is that neurosyphilis is due to invasion of the nervous system by a spirochete. The deleterious effect of trauma on the pathologic process of neurosyphilis can only be deduced. There is divergence of opinion about the severity of trauma necessary and the time interval that must elapse between the injury and the appearance of symptoms.

In a review of tabetic arthropathies, Steindler, Williams and Puig-Guri⁴³ analyze the findings in 134 cases in which there were two hundred and fourteen Charcot's joints. A definite picture of tabes was present in only 57 of these cases. The age limits were from seventeen to eighty-two years. Of these patients 97 per cent were men. Various injuries preceded the onset of arthropathy in 59 cases (44 per cent). The time interval between the acquisition of syphilis and the onset of joint symptoms varied between five and ten years. These cases were analyzed from numerous aspects for statistical purposes. There were only 5 cases in which the joints of the upper extremities were involved. The knee was the most frequently affected joint (51 per cent of all joints, or 64 per cent of the 134 patients). Ten cases became complicated with pyogenic infection through ulcers and local sores, and all but 2 of these came to amputation. These authors believe that trauma is never the cause of syphilitic arthropathy but is undoubtedly of contributing importance in its development. It is pointed out that normal fractures may occur in a tabetic patient or in one suffering from syringomyelia, and may be produced by a perfectly adequate and plausible traumatic event.

CONGENITAL SYPHILIS

An interesting point of differential diagnosis has been discussed by Henderson.⁴⁴ Over a five-year period he observed 53 infants with erythroblastosis. Ten were stillborn, 24 died, and 19 recovered. Autopsies were performed on all 34 fatal cases. Henderson points out that the two severest forms of erythroblastosis, hydrops fetalis and hepatic cirrhosis, occur in connection with intrauterine death and are usually mistaken for congenital syphilis. A large, pale placenta occurs in both these diseases. Uncertainty will seldom arise if certain points are considered in all doubtful cases. The occurrence of a proved case in an older sibling makes the diagnosis almost certain. Congenital syphilis becomes progressively less severe in each succeeding pregnancy; in erythroblastosis the trend is opposite. The frequency and degree of prematurity are much higher in syphilitic infants than in those with erythroblastosis. The gross appearance of the placenta may be strikingly similar, but syphilitic placentas usually show areas of infarction. Osseous manifestations are absent in erythroblastosis. The

demonstration of *Treponema pallidum* in the tissues of the fetus, cord or placenta dispels doubt; it can often be found by immediate scrapings of the intima of the umbilical vein. Microscopical examination of tissue is, of course, of great assistance, but occasions some delay.

For practical purposes it is generally considered that one can disregard the possibility of cardiovascular syphilis in congenital cases. An exhaustive review of this problem has been published by Hinrichsen.⁴⁵ The literature has been painstakingly searched, and reported cases are discussed. Hinrichsen found reports of various types of vascular syphilis, with the exception of valvular heart lesions. Although congenital syphilitic aortitis, with or without aneurysm, has been reported, this author found no case on record with syphilitic valvular lesions of the heart. Congenital syphilitic myocarditis of interstitial and nodular types has been described but its incidence is uncertain. Autopsies on stillborn or early post-natal fatalities are almost the only cases recorded. The role of syphilis in the production of congenital malformations of the heart has not been determined. Congenital syphilis as a cause of hemorrhagic disease of the newborn is also mentioned in this paper.

A study of the possible effect of bismuth on the growth of children has been made by Russin, Stadler and Jeans.⁴⁶ It is reasonable to assume that there may be interference with growth, since the abnormal changes observed roentgenographically after the administration of bismuth appear at the sites of provisional ossification of growing long bones. These authors followed 10 children under treatment for congenital syphilis for periods as long as ten years. Their actual heights were compared periodically, with the predicted height, and the average difference in most cases was practically zero. The conclusion was drawn that, although the roentgenographic changes observed represent abnormalities of bone growth, the prolonged administration of bismuth does not interfere with the rate of linear growth.

The intramuscular method of administration of Mapharsen has been utilized by Astrachan and Cornell⁴⁷ in congenital syphilis. Sixty-eight patients with various stages of congenital syphilis, as well as 19 with latent acquired syphilis, were treated. Most of those with early congenital syphilis were treated by the intramuscular route, and the rest intravenously. The majority of the patients tolerated well the intramuscular injections of Mapharsen and showed no untoward reactions. Clinical and serologic results were satisfactory. These authors believe that the concurrent administration of Mapharsen and bismuth is often valuable in late congenital syphilis. They think that 0.75 mg. per kilogram of body weight should be the maximum dosage for any patient with congenital syphilis.

Levin, Hoffman, Koransky, Richter and Gumbiner⁴⁸ have applied the principles of massive therapy

to the treatment of syphilis in infants and children. Thirty-two cases of congenital syphilis and 4 in children with the acquired disease were given the five-day treatment with Mapharsen. The authors properly stress the importance of adequate pediatric care during this procedure. No serious toxic reactions or deaths occurred. The 4 cases of acquired infection promptly became seronegative; the congenital cases were notably inferior in response when compared to those of early acquired syphilis in adults. This led the authors to believe that congenital syphilis produces widespread changes more resistant to treatment than acquired syphilis. In considering this, one would hardly expect anything else unless only selected cases of early congenital syphilis in children (from birth to the age of six months) were treated. Otherwise, they would not be comparable to those of early syphilis in adults.

THERAPY

Penicillin

At the seventy-second annual meeting of the American Public Health Association, Mahoney, Arnold and Harris⁴⁹ reported favorable results in the treatment of 4 cases of early syphilis exclusively with penicillin. Each received 1,200,000 units of the drug in eight days. Dark-field examinations became negative about seven hours after the treatment was begun. Lesions were healed within two weeks. Serologic tests for syphilis became negative within thirty days. At the time of this writing, these patients had remained negative for approximately eight months. This is indeed a most startling report, and certainly one may hope for a great advance with the use of such a remarkable drug. As often before mentioned, however, caution must be exerted in predicting any results with new treatment for syphilis. It will take several years to determine whether penicillin is generally indicated in this disease. It may take ten or more years to tell whether its results are lasting. Dr. Mahoney himself, in reading this paper, urged caution in interpreting results. It is to be remembered that penicillin is not available for general use and that only a limited amount can be spared for the study of syphilis at this time.

Other Drugs

Trisodarsen. A résumé of eight years' experience with Trisodarsen has been published by Beerman, Pariser and Gordon.⁵⁰ The results of treatment of 550 patients in various stages of syphilis were analyzed. Forty-four per cent had reactions, although the majority of them were mild. Infectious and serologic relapses occurred in 10 per cent of 177 patients with early syphilis. This compared favorably with the Co-operative Clinical Group statistics of 10.1 per cent. In all other respects the results were comparable to those expected with drugs in common use, but the authors state that their patients have not been observed long enough to

valuate definitely the probabilities of cure of syphilis from this drug, although the trend appears to be favorable. The main drawback seems to be an apparent tendency of this compound to induce dermatitis.

Phenarsine hydrochloride. Two preliminary reports have appeared on the treatment of syphilis with phenarsine hydrochloride. Long⁵¹ subjected 96 patients to treatment with this drug. It was administered in a standardized manner, with bismuth in alternate series. Open lesions were rapidly sterilized, and healed satisfactorily. There was no case of elapse. The rapidity of serologic reversal was on the whole satisfactory. There was a low incidence of abnormal spinal fluids among the patients with early syphilis. The drug was well tolerated in late syphilis and the response was good. Guy, Goldmann and Gannon⁵² have also used phenarsine hydrochloride. These investigators worked out data on toxicity and cures in rats according to standard procedures. The results did not differ materially from those obtained with Mapharsen. Two hundred and thirty-three patients were subsequently treated by a standard continuous program with alternate courses of bismuth. The results were comparable to those of Long.⁵¹ Guy, Goldmann and Gannon also believe that phenarsine hydrochloride compares favorably with other drugs that are now in general use and think that it may prove more stable. Forty milligrams of the drug was administered daily for twenty-five successive days to a woman patient. The secondary cutaneous lesions disappeared at the end of ten days, and the patient tolerated the drug without any ill effects.

Clorarsen. Clorarsen has been used in the treatment of syphilis by Kampmeier and Henning.⁵³ Two hundred and fifty patients with early syphilis were treated, with satisfactory response in all respects. A standard continuous program, with alternating courses of bismuth, was employed. A single therapeutic dose produced dark-field negativity within twenty-four hours in 42 of the 45 infectious cases. No serious untoward reactions were encountered. The drug was used often without reaction in patients who had had difficulty with other arsenical preparations. The experimental use of clorarsen seems to indicate that it is effective in acute syphilis, is attended by few reactions, and may be used as an alternate drug in patients who have had reactions to other arsenical drugs.

Bismarsen. A review of fourteen years' experience with Bismarsen has been published by Beerman, Shaffer and Livingood.⁵⁴ Eight hundred and twenty-three syphilitic patients were treated with the drug during this time. All stages of the disease were included. The authors state that Bismarsen is a relatively nontoxic drug. It was frequently used in treating patients who had had unfavorable reactions to other arsenicals. This experience seems to be at variance with that of other syphilotherapists.

Perhaps more statistical study would prove these authors correct, but it seems to be a common impression that patients intolerant to intravenous arsenotherapy are more likely to develop reactions when Bismarsen is administered. Beerman, Shaffer and Livingood found that the lesions of early syphilis healed more slowly under Bismarsen therapy than under other arsenicals and that its spirillicidal action was slower. They consider it a safe and effective drug for the treatment of cardiovascular syphilis. The action of Bismarsen was found to be too slow for use against interstitial keratitis. The authors believe that it is not the drug of choice for neurosyphilis, but that for persons for whom fever therapy and other forms of chemotherapy are contraindicated it is a useful substitute. One would be justified in thinking that Bismarsen is not the drug of choice but a secondary measure primarily suitable for those in whom intravenous therapy is not feasible.

Bismuth. Two additional reports have appeared concerning the tempering effect of bismuth on therapeutic malaria. This phenomenon was mentioned in a previous progress report.⁵⁵ Thio-Bismol is the preparation employed. It has proved extremely useful in the hands of Whelen and Shute.⁵⁶ These authors found that an injection of 0.2 gm. of Thio-Bismol was effective in stopping malarial paroxysms for forty-eight hours, the drug having a selective action on alternate cycles of benign tertian malaria during the developed stage. If administered during the incubation period the drug did not appear to have any effect on the time of onset or type of fever. Proper use of this procedure can extend the range of cases that can be treated and may be of great assistance in certain emergencies. Young, McLendon and Smart⁵⁷ have had similar experience with Thio-Bismol. These authors found that the inhibitory effect against *Plasmodium vivax* was most marked when the parasites were half grown — that is, sixteen to twenty-four hours after the last paroxysm. Older or younger parasites might not be affected at all. Other species, such as *P. malariae* and *P. falciparum*, were uninfluenced by Thio-Bismol. For the termination of *P. vivax* infections, these authors found that one injection of the drug, given on the day quinine was started, usually acted more quickly than did quinine alone by preventing a paroxysm the following day.

The importance of oral hygiene during bismuth therapy has long been known. It is a prophylactic measure that serves to ward off oral complications that may be most disturbing. Dean⁵⁸ has published a report that serves to emphasize this fact. A dark line on the gums, bleeding of the gums, excessive salivation, a bad odor of the breath, puffing and swelling of the gum tissue and an occasional loosening of the teeth were found to be remarkably improved by mouth care in the hands of dental clinics. Test cases were developed by giving general dental

care to half the lower jaw of patients showing symptoms of bismuth stomatitis. The other half of the lower jaw was not treated. There is much that the patient can do at home in the way of general mouth hygiene, gum massage and so forth. Analysis of the black deposit at the gingival margins indicates that it is probably bismuth sulfide. Dean believes that it is not necessary to interrupt or discontinue the use of bismuth treatment if adequate dental service is given before or during the periods of injection. These are well-known facts, but repetition seems worth while at this time. Dean's procedure in treating only half of one jaw provided an unquestionably satisfactory control.

Intensive Therapy

Although complications were frequent and comparatively serious with earlier attempts at massive therapy, gradual improvement and modifications of technic have slowly created a more favorable situation. Eagle and Hogan⁵⁹ have approached this problem from the experimental standpoint through a study of toxicity and excretion of Mapharsen in rabbits. Various programs of multiple injections and intravenous-drip administration were used. It was found that the total amount of Mapharsen tolerated by the animals is apparently without limit, with suitable prolongation of the treatment period. It was found possible by increasing the frequency of injections to increase significantly the amount of Mapharsen that can be administered with safety within a given period. In a continuation of this study, Eagle and Hogan⁶⁰ worked out the therapeutic efficiency and margin of safety of Mapharsen in the treatment of rabbit syphilis. The curative dose of the drug was largely unaffected by the method of administration. Multiple-syringe techniques were more effective than intravenous drip procedures. The margin of safety between the toxic and therapeutic dose could be increased by appropriate prolongation of the treatment period. An appreciable condensation of treatment beyond that permitted by triweekly, daily or multiple daily injections can be accomplished only at the cost of safety by an arbitrary decrease in the total number of injections. In a third article of this series Eagle and Hogan⁶¹ discuss the clinical implication of their experimental work. An optimal treatment schedule was worked out for the management of early syphilis in the human being. This was based on the experimental animal data and published reports on the treatment of human syphilis. Without exception, and despite the reservations that must be applied to a chemotherapeutic index based on a toxicity study in animals, the observed incidence of serious toxic reactions and death has varied inversely with the calculated margin of safety. A triweekly schedule of Mapharsen injections was worked out as having a satisfactory margin of safety. Dosage was calculated on a body-weight basis (1 mg. per kilogram), and

treatment was continued for a period of four to twelve weeks. The four-week schedule proved inadequate, as was predicted. The other schedules were continued. Approximately half the patients received weekly injections of bismuth to determine to what extent that drug would modify the end results. More than eighty marine hospital and university, municipal and state health-department clinics are now co-operating in this study. At the time of Eagle's report 2500 patients had been treated. The detailed analysis of the initial results will be described in a later paper. Another observer, Shaffer⁶² has evaluated the published reports on massive therapy from a clinical standpoint. He believes that intensive methods of treatment should still be considered experimental, and warns against the attempted use of such procedures by physicians without extensive experience. As further information is accumulated, it is expected that the experience of well-controlled work will permit the establishment of a definite procedure to be recommended in the not too distant future for use in private practice. Intensive therapy in various types of latent and late syphilis is far behind that of early syphilis. I cannot agree too heartily with Shaffer's opinions.

Combined Fever and Chemotherapy

In last year's progress report⁶³ attention was called to promising results with the use of a single artificial-fever treatment combined with chemotherapy in one intensive session for early syphilis. A subsequent report by the same authors, Thomas, Wexler, Shur, and Goldring,⁶⁴ described a serious renal complication. Forty-eight patients were treated under a two-day schedule consisting of two intravenous injections of Mapharsen on the first day, followed on the second day by two more with seven hours of artificially induced fever. Four of these patients developed acute nephrosis and 4 others severe albuminuria, together with azotemia of brief duration. All eight recovered from the acute episode. The cases were described in detail and were doubtless extremely alarming. The authors believe that the complication in these patients was an acute nephrosis induced by the combination of arsenic and prolonged use of artificial fever. This emphasizes the caution required in evaluating the safety of heroic experimental treatment of syphilis.

REACTIONS TO THERAPY

Hepatitis

Jaundice occurring during the course of anti-syphilitic therapy has been a source of concern to a great many observers. Two series of cases reported within the last year seem of interest. Kulchar and Reynolds⁶⁵ have published a survey of 144 cases. They postulate the usual causes of jaundice as intercurrent infection, arsenic intoxication or hepatorecurrence. Their cases occurred among 1032

syphilitic prison inmates, the incidence being rather high (13.9 per cent). Kulchar and Reynolds were studying hepatitis primarily from the standpoint whether bismuth was the etiologic agent, but only 3 of their cases had been treated with bismuth alone; 3 followed within four to eight weeks after the termination of arsenical therapy, and 56 within eight or more weeks. Treatment was subsequently resumed in 107 patients, 9 of whom developed a second attack of jaundice. In 4 of these cases the attack followed bismuth, and in 5 arsenic. These authors believe that previous arsenical therapy, diet, alcohol and intercurrent infection may predispose the patient to liver damage from the administration of bismuth. In other words, a summation effect of several factors, all individually unable to produce hepatitis, is proposed. Bismuth is thus placed in the role of precipitating the attack of jaundice. In the end, however, Kulchar and Reynolds favored the preceding arsenotherapy as of considerable importance. Syphilotherapists in general might question the frequency of a precipitating effect of bismuth in jaundice. It cannot be denied, however, that bismuth may create some liver damage or that it could be the last straw, so to speak, in the face of pre-existing liver damage. Ottenberg and Spiegel⁴⁶ have written on the present status of nonspecific jaundice due to infectious and chemical agents. They think that disease of the hepatic parenchyma may be due directly or indirectly to infection or to chemical agents. In their experience, clinical features of single cases are of little help in determining etiology, and tests of hepatic function have from the etiologic standpoint been largely fruitless. It is pointed out that syphilis is one of the infectious diseases that can cause hepatitis. It is stated that half the fatal cases of congenital syphilis show liver involvement, that some evidence of syphilis of the liver is found in approximately 1 per cent of secondary syphilis, and that about 10 per cent of the severer cases progress to acute yellow atrophy. Arsenic is said to belong to the group of drugs considered hepatotoxic, and the mechanism is considered to be one of idiosyncrasy, hypersusceptibility or allergic sensitivity. Since syphilis itself can damage the liver, and its most powerful antidote is hepatotoxic, the disease together with arsenotherapy could certainly be expected to produce liver damage from time to time. Ottenberg and Spiegel found reports in the literature quoting the incidence of so-called "arsenical jaundice in syphilotherapy" as approximately 1 per cent or less. Comparing these figures with those of Kulchar and Reynolds,⁴⁵ one would suspect that the prison inmates treated by the latter may have been strongly influenced by intercurrent infection of epidemic proportions. Ottenberg and Spiegel believe that bismuth is possibly a hepatotoxic drug, but that it is far weaker in that respect than is arsenic.

Kopp and Solomon⁴⁷ have studied the effect of prolonged trypanamide therapy on liver function. Their material consisted of 66 patients with syphilis of the central nervous system. In most cases the drug was given weekly in 3-gm. doses. One patient had received the amazing total of five hundred and thirty-nine injections of trypanamide. A number of them had also been treated with bismuth, trivalent arsenical therapy, or mercury or some form of fever therapy or both. Normal liver function was found in 16 of the patients. The remaining 50 revealed abnormal findings in one or more tests. Studies included the bromsulfalein test, phospholipids, fibrinogen, cholesterol esters, hippuric-acid excretion, icteric index, bilirubin, the van den Bergh reaction and the cephalin flocculation test. Abnormalities were slight enough to lead these authors to conclude that trypanamide causes relatively little liver damage even when given over a long period of time (as long as eighteen years) and combined with fever therapy. Jaundice occurring during therapy under all these circumstances is considered by Kopp and Solomon to cause no important damage to the liver and is not held to be a contraindication to the further use of trypanamide. It is sometimes surprising how much the human organism can tolerate.

Arsenical Reactions

Robinson⁴⁸ discusses reactions to arsphenamine from the standpoint of their effect on syphilis as well as on the patient. Severe exfoliative dermatitis and hepatitis have been thought at times to have a favorable influence on the course of the disease. Robinson reviews the cases of 381 patients who recovered from these complications and were followed for three months to twenty-one years. He found no evidence that severe treatment reactions of any sort play a part in the cure or amelioration of syphilis. He does not believe that arsenotherapy should be withheld from the patient who has seborrheic, atopic, contact or other itching dermatoses. This sounds a little dogmatic. It has been a matter of common observation that severe and extensive dermatoses may indeed be exacerbated by arsenotherapy and may progress to universal exfoliative dermatitis. Robinson outlines measures to avoid reactions of all types, the management of reactions and the factors to be considered before resumption of therapy, if it is to be resumed. He emphasized the well-known fact that exfoliative dermatitis is a positive contraindication to further arsenotherapy.

A method of circumventing reaction to arsenical drugs is described by Beerman, Pariser and Wani-mock.⁴⁹ The many reports in recent years regarding the possible value of vitamin C in the prevention of reactions led these investigators to study various solvents containing vitamin C for use as diluents in administering arsenic intravenously. Methylglucamine ascorbate was found to be the

most useful solvent. A 7 per cent solution of sucrose was utilized as the diluent. One hundred and fourteen patients who had exhibited some sort of reaction, usually mild, that on occasion necessitated the discontinuance of arsenical therapy were treated. This mixture seemed to have a beneficial effect on about half the patients who had had nausea and vomiting or nitritoid crises. One hundred milligrams of the ascorbic acid derivative was found to be the optimal dose.

Stephenson, Chambers and Anderson⁷⁰ report the annual statistics of the United States Navy on the toxic effects of arsenical compounds. One fatality from Mapharsen (from cerebral hemorrhage) is included in the current report. Total reactions from Mapharsen averaged one third as many as from neoarsphenamine. Dermatitis comprised 45 per cent of the total reactions, as compared with 55 per cent in the preceding year. The type of lesion was erythematous in 3 cases, exfoliative in 3 and macular, maculopapular, morbilliform and scarlatiniform in 1 each. Six cases of these dermatoses were mild, and 4 were severe.

Bismuth Eruptions

This subject is interesting, and it is doubted whether the average physician realizes either the frequency or the variety of dermatoses that can occur during bismuth therapy. Noojin and Callaway⁷¹ have reported on the subject of bismuth eruptions in antisyphilitic therapy. Acute eruptions are listed as erythematous, exfoliative, scarlatiniform, urticarial, purpuric and multiform and as similar to those of herpes zoster. Chronic bismuth eruptions may assume a pityriasis rosea type, lichen planus type, lichen simplex chronicus type (neurodermite), a fixed eruption or a generalized chronic eczematoid dermatitis. It should be emphasized that none of these are commonly observed. For that reason their occurrence may be confusing to those not treating large numbers of patients with syphilis.

SUMMARY

Although this year's report seems of considerable interest in its totality, a few items will bear re-emphasis.

Perhaps one of the most remarkable matters is the failure to follow up blood donors who have been found to have a positive serologic test for syphilis. It seems imperative that some means be found for all hospitals to do better with the problem. Other reports concerning the public-health aspect of syphilis control that are of considerable interest include good results in the operation of the Connecticut law governing premarital blood tests, the consultation program for local physicians provided by the State of New York, the so-called "facilitation process" employed in British Columbia to get at the source

of venereal disease and an encouraging reduction of the incidence of syphilis in the Army.

Syphilis in industry has received considerable mention in the recent literature. An outstanding example of the effectiveness of syphilis control in this field is the plan in use at the Remington Arms Company.

A most hopeful advance in the field of therapy is the use of penicillin for the treatment of syphilis. It is naturally too soon to go farther than to mention the possible successful treatment with this powerful drug. Considerable work is being continued in the field of intensive therapy, with various modifications in methods and encouraging results. The matter of increased reinfections following massive therapy is becoming of some importance.

The experimental use of arsenical drugs by intramuscular and oral administration in the treatment of syphilis seems hopeful. Should these procedures prove satisfactory, they would greatly enhance the ease of administration and the co-operation of patients.

CASE 30051

PRESENTATION OF CASE

An eighteen-year-old youth entered the hospital because of high blood pressure.

The patient was in excellent health until about seven months before admission, at which time he noticed the onset of occasional headaches. He had cold feet and legs at night, accompanied by hot flashes over the upper half of the body. Three months prior to entry he developed persistent nocturia, twice a night. There were one or two short episodes of dysuria, but no polyuria, pyuria, hematuria or incontinence. For years he had drunk two quarts of water daily. He had no increased thirst. About one month before admission he developed a sharp, occipital pain, which was accompanied by a dull ache over his eyes and over the bridge of his nose. At first the pain came on in the morning on waking, was relieved by work and returned in the afternoon or evening. Lately it had become persistent and prevented him from sleeping. About three weeks before admission, while being examined for a job, he was told that he had high blood pressure. The headaches became quite severe. Two days before admission he woke with a right facial paralysis. He had a slight nosebleed and palpitation, with slight nonradiating precordial pain, blurring of vision and mental confusion. He was unable to recognize his father. He had no vertigo, convulsion, unconsciousness, nausea, vomiting, fever, chills or anginal pains. He had lost 13 pounds of weight in two years.

The past history was entirely negative except for diphtheria as a child.

Physical examination showed a well-developed, well-nourished man in no distress. The lungs were clear. The left border of cardiac dullness was 8 cm. from the midsternal line in the fifth space. The sounds were forceful, regular, and of good quality. A loud third sound and a split second sound were heard at the base. The aortic second sound was greater than the pulmonic. There was complete right facial paralysis. No spasm, anesthesia or paresthesia was noted. The fundi showed rather marked generalized spasm. The disk margins were blurred, but there were no elevations; a few collections

*On leave of absence.

of cotton-wool exudate were seen, as well as two or three small bits of waxy exudate, in the left macula. Neurologic examination was otherwise negative except for bilaterally decreased tendon reflexes.

The blood pressure was 190 systolic, 140 diastolic. The temperature was 98.6°F., the pulse 80, and the respirations 20.

Examination of the blood showed a red-cell count of 5,700,000, with 14.5 gm. of hemoglobin. The white-cell count was 14,500, with 66 per cent neutrophils. The urine showed a specific gravity of 1.020. There were three or four red cells and one or two white cells in the sediment. The culture was negative. The stools were guaiac negative. A blood Hinton test was negative. The nonprotein nitrogen was 28 mg. per 100 cc.

X-ray examination of the chest showed slight enlargement of the left ventricle. An intravenous pyclogram was negative. A urine concentration test showed a specific gravity of 1.022. A phenol-sulfonephthalein test revealed 40 per cent excretion in the first fifteen minutes, and 85 per cent in two hours. A lumbar puncture gave an initial pressure of 120 mm. of water; 10 cc. of clear colorless fluid was withdrawn, with a final pressure of 80 mm. There were 3 white cells per cubic millimeter, with a total protein of 82 mg. per 100 cc. The gold-sol test was 0011331000. Repeated blood-pressure determinations gave an average of 200 systolic, 140 diastolic, while lying down and sitting, and one of 150 systolic, 130 diastolic, while standing. The entire determination, however, was done in a single sitting over a period of only twenty-four minutes. A cold pressor test showed a systolic rise of 10 mm. and a diastolic rise of 10 mm. Blood-pressure determination after the administration of three doses of 3 gr. of sodium amytal within a period of three hours showed no definite change. An electrocardiogram revealed a normal rate of 85. The PR interval was 0.12 second; S₂ and S₃ were prominent; ST₂ and ST₃ were depressed, with increased T₂ and T₃.

The patient's condition remained essentially the same. There was a slow rise of blood pressure. On the sixth hospital day he developed a sore throat, with chilly sensations and increased sweating. The temperature rose to 102°F. Examination showed a beefy-red throat and bilaterally tender and enlarged posterior cervical lymph nodes. The white-cell count was 13,800, with 78 per cent neutrophils. A throat culture showed many beta-hemolytic streptococci. On the sixteenth hospital day he was given 2 gm. of sulfadiazine every two hours for two doses, followed by 1 gm. every four hours for six days. The throat culture became negative.

On the twenty-first hospital day he complained of discomfort in the right flank. There was some tenderness in the right costovertebral angle. The urine examination showed a specific gravity of 1.010 and a + test for albumin. The urine contained innumerable red cells, with occasional white cells and

granular casts, which persisted for five days. A urine culture was negative. The temperature, pulse and respirations were normal. The blood pressure was 220 systolic, 165 diastolic.

An operation was performed on the twenty-sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. HARRY A. DEROW*: We are dealing with an eighteen-year-old boy with severe progressive arterial hypertension and without any history of antecedent renal or hypertensive disease. The onset of this condition apparently dated from about seven months prior to admission to this hospital. Because of the high diastolic pressure and the retinal picture of papilledema, cotton-wool spots and diffuse arteriolar spasm, we have to make a diagnosis of malignant hypertension. By making this diagnosis we are not referring to any specific pathologic process in the kidneys; that is, the term "malignant hypertension" is used as a clinical diagnosis.

Back in 1935, Dr. Mark Altschule and I¹ pointed out that malignant hypertension is a syndrome that may occur with no evidence of existing hypertension, as the end stage of primary (essential) hypertension or as the end stage of a miscellaneous group of conditions characterized by secondary hypertension. We also pointed out that during the life of the patient exhibiting the syndrome of malignant hypertension it is usually difficult if not impossible to determine the nature of the underlying pathologic process, that the prognosis by and large of these patients is extremely poor and that the cases that offer some modicum of hope are those rare surgically amenable cases in which the syndrome has been precipitated by renal infarction or by the development of certain tumors of the adrenal gland (pheochromocytomas). Also, there are cases of malignant hypertension that despite the poor prognosis, develop spontaneous remissions, during which the fundi show amazing improvement. The blood pressure, however, remains the same and these patients may go on for a period of years only to succumb to the same rapidly progressive picture that they originally presented.

In this patient, what evidence do we have to indicate antecedent primary inflammatory renal disease? I should like to ask about the urine examinations. The number of examinations done is not given; also the presence or absence of albumin is not stated.

DR. BENJAMIN CASTLEMAN: A + and a ++ test were recorded in three out of nine examinations.

DR. DEROW: The fact that six of the nine urine specimens that were examined failed to show albumin makes me believe that we are probably not dealing with primary inflammatory renal disease upon which malignant hypertension has been super-

imposed.³ I am unable to interpret the history of one or two short episodes of dysuria three months before entry, particularly since there was no pyuria, hematuria or incontinence. On the other hand, it is possible for patients with chronic inflammatory renal disease causing albuminuria to go along for many years without symptoms of any kind, with intact kidney function and with normal blood pressure, only to develop suddenly the picture that this patient presented. The normal intravenous pyelogram probably rules out polycystic kidneys or other congenital anomalies of the upper urinary tract. The possibility of an adrenal tumor cannot be eliminated by the finding of a normal pyelogram, and that of course is a possibility here. There is no mention made of scalloping of the ribs or of the blood-pressure values of the legs, so I think that we can probably eliminate coarctation of the aorta.

The possibility of a brain tumor is unlikely, because the patient presents the picture of scattered focal lesions in the cortex, midbrain, and pons, and it is difficult to visualize a brain tumor that would involve such dispersed areas. My explanation for the cerebral picture is that there were scattered necrotic vascular foci, which are often seen in patients with severe hypertension.

We are left with the diagnosis of the syndrome of malignant hypertension without any clear idea of the underlying renal lesion. There does not seem to be any impairment of renal or cardiac function, and the clinical picture is chiefly that of cerebral disease.

The clinical course of the patient is interesting. On the sixth day, he developed a streptococcal sore throat, and because of the persistence of a positive throat culture, he was given sulfadiazine. There is a question, of course, whether the throat culture would not have become negative in the course of time and whether sulfadiazine should have been given in the absence of active streptococcal infection. There is a difference of opinion on this matter. Not so long ago I had occasion to discuss with Dr. Maxwell Finland the matter of the administration of sulfadiazine to patients in the carrier state, and he is one who believes that sulfadiazine should not be given. The attending physicians probably wanted to eliminate the throat as a source of infection as quickly as possible prior to whatever operative procedure was going to be undertaken. During the course of the sulfadiazine therapy the patient developed discomfort in the right flank, tenderness in the right costovertebral angle, albuminuria, hematuria, pyuria and cylindruria. There is no mention made of the development of edema, nor of the urinary volume, during this period of what seems to be a renal complication following the administration of sulfadiazine. Is there any information in that regard?

DR. CASTLEMAN: No.

DR. DEROW: The note does appear, however, that the diastolic pressure was elevated above the levels that were previously recorded. From the history

CASE 30051

PRESENTATION OF CASE

An eighteen-year-old youth entered the hospital because of high blood pressure.

The patient was in excellent health until about seven months before admission, at which time he noticed the onset of occasional headaches. He had cold feet and legs at night, accompanied by hot flashes over the upper half of the body. Three months prior to entry he developed persistent nocturia, twice a night. There were one or two short episodes of dysuria, but no polyuria, pyuria, hematuria or incontinence. For years he had drunk two quarts of water daily. He had no increased thirst. About one month before admission he developed a sharp, occipital pain, which was accompanied by a dull ache over his eyes and over the bridge of his nose. At first the pain came on in the morning on waking, was relieved by work and returned in the afternoon or evening. Lately it had become persistent and prevented him from sleeping. About three weeks before admission, while being examined for a job, he was told that he had high blood pressure. The headaches became quite severe. Two days before admission he woke with a right facial paralysis. He had a slight nosebleed and palpitation, with slight nonradiating precordial pain, blurring of vision and mental confusion. He was unable to recognize his father. He had no vertigo, convulsion, unconsciousness, nausea, vomiting, fever, chills or anigral pains. He had lost 13 pounds of weight in two years.

The past history was entirely negative except for diphtheria as a child.

Physical examination showed a well-developed, well-nourished man in no distress. The lungs were clear. The left border of cardiac dullness was 8 cm. from the midsternal line in the fifth space. The sounds were forceful, regular, and of good quality. A loud third sound and a split second sound were heard at the base. The aortic second sound was greater than the pulmonic. There was complete right facial paralysis. No spasm, anesthesia or paresthesia was noted. The fundi showed rather marked generalized spasm. The disk margins were blurred, but there were no elevations; a few collections

of cotton-wool exudate were seen, as well as two or three small bits of waxy exudate, in the left macula. Neurologic examination was otherwise negative except for bilaterally decreased tendon reflexes.

The blood pressure was 190 systolic, 140 diastolic. The temperature was 98.6°F., the pulse 80, and the respirations 20.

Examination of the blood showed a red-cell count of 5,700,000, with 14.5 gm. of hemoglobin. The white-cell count was 14,500, with 66 per cent neutrophils. The urine showed a specific gravity of 1.020. There were three or four red cells and one or two white cells in the sediment. The culture was negative. The stools were guaiac negative. A blood Hinton test was negative. The nonprotein nitrogen was 28 mg. per 100 cc.

X-ray examination of the chest showed slight enlargement of the left ventricle. An intravenous pyelogram was negative. A urine concentration test showed a specific gravity of 1.022. A phenol-sulfonephthalein test revealed 40 per cent excretion in the first fifteen minutes, and 85 per cent in two hours. A lumbar puncture gave an initial pressure of 120 mm. of water; 10 cc. of clear colorless fluid was withdrawn, with a final pressure of 80 mm. There were 3 white cells per cubic millimeter, with a total protein of 82 mg. per 100 cc. The gold-sol test was 0011331000. Repeated blood-pressure determinations gave an average of 200 systolic, 140 diastolic, while lying down and sitting, and one of 150 systolic, 130 diastolic, while standing. The entire determination, however, was done in a single sitting over a period of only twenty-four minutes. A cold pressor test showed a systolic rise of 10 mm. and a diastolic rise of 10 mm. Blood-pressure determination after the administration of three doses of 3 gr. of sodium amytal within a period of three hours showed no definite change. An electrocardiogram revealed a normal rate of 85. The PR interval was 0.12 second; S₂ and S₃ were prominent; ST₂ and ST₃ were depressed, with increased T₂ and T₃.

The patient's condition remained essentially the same. There was a slow rise of blood pressure. On the sixth hospital day he developed a sore throat, with chilly sensations and increased sweating. The temperature rose to 102°F. Examination showed a beefy-red throat and bilaterally tender and enlarged posterior cervical lymph nodes. The white-cell count was 13,800, with 78 per cent neutrophils. A throat culture showed many beta-hemolytic streptococci. On the sixteenth hospital day he was given 2 gm. of sulfadiazine every two hours for two doses, followed by 1 gm. every four hours for six days. The throat culture became negative.

On the twenty-first hospital day he complained of discomfort in the right flank. There was some tenderness in the right costovertebral angle. The urine examination showed a specific gravity of 1.01 and a + test for albumin. The urine contained innumerable red cells, with occasional white cells and

*On leave of absence.

nucleate from the adrenal gland. A renal biopsy was also performed.

Microscopically the tumor is a pheochromocytoma, — a tumor of the medulla, — but it is of an unusual type. The cells are arranged in a pattern somewhat reminiscent of a neuroblastoma (Fig. 1). I suppose it is possible to have a tumor containing both these types of cells, since originally they arose from the same sympathetic primitive cell or sympathogonia.

DR. DEROW: Did you find acute hemorrhage in the tumor to explain the development of the symptoms that the patient had?

DR. CASTLEMAN: No; just foci of necrosis that you may find in any actively growing tumor.

DR. R. H. SMITHWICK: What did the renal biopsy show?

DR. CASTLEMAN: A perfectly normal kidney, with no evidence of arteriolar disease.

This patient has been well and free from hypertension since his operation two years ago, and a sympathectomy was not necessary on the other side. The cause of his hypertension, therefore, although it was not of the paroxysmal type, was the adrenal tumor.

DR. REGINAID H. SMITHWICK: This case is one of the few with pheochromocytoma without paroxysmal hypertension. I think it is well to stress the fact that this is an extremely rare condition. The great majority of reported cases with pheochromocytoma have had definite paroxysmal hypertension. So far as I know there are only one or two cases in the literature that in any way compare with this one; hence, it is difficult to make a diagnosis of pheochromocytoma in the absence of paroxysmal hypertension.

CASE 30052

PRESENTATION OF CASE

First admission. A sixteen-year-old schoolgirl was admitted because of high blood pressure.

The patient had pseudoarthrosis of the left leg at the age of three, and several operations were performed in various community hospitals. She had diphtheria, measles, chickenpox, whooping cough, tonsillitis and pneumonia as a child, but no history of kidney disease was known. Five months before entry she had an attack of dizziness, headache and unconsciousness, resulting in "complete left hemiplegia." Prior to that time the determination of her blood pressure was of questionable veracity, but one determination eighteen months previously was reported as "112." She was admitted to a community

hospital, where the blood pressure was found to be 180 systolic, 120 diastolic. There was a complete left hemiplegia, with slowing of the speech. The spinal fluid was grossly bloody. During the course of the next three weeks the fluid gradually cleared, and the patient began to have some return of function in the arm and leg. The blood-pressure readings varied between 240 systolic, 180 diastolic, and 180 systolic, 110 diastolic. She was found to have a urinary-tract infection and was put on "adequate dosage of sulfadiazine." A urine-concentration test performed at that time showed a fixed specific gravity of about 1.010. A phenolsulfonephthalein test showed 70 per cent excretion in two hours, with 20 per cent in the first twenty minutes. An insulin tolerance test was normal. The paralysis of the face and slurring of the speech disappeared, and there was some improvement in the left leg and arm. She was then transferred to this hospital.

Physical examination showed a well-nourished girl with many brown nevi scattered over the entire body. There was a dorsal scoliosis. The left leg was 7.5 cm. shorter than the right. Excessive hair was present over the arms, legs and abdomen. The heart and lungs were normal. There was deep tenderness in the left flank, and a feeling of fullness, but no masses. Neurologic examination showed papilledema, old and new retinal hemorrhages and albuminuric spots. She was unable to count fingers with either eye. There was a left hemiparesis, and spasticity of the left leg with hyperactive reflexes. The Hoffmann, Oppenheim, Chaddock and Babinski signs were positive on the left.

The blood pressure was 160 systolic, 120 diastolic. The temperature was 99°F., the pulse 80, and the respirations 20.

Examination of the blood showed a red-cell count of 4,610,000, with 13.8 gm. of hemoglobin. The white-cell count was 6500, with 68 per cent neutrophils. A blood Hinton test was negative. The urine was cloudy, with a pH of 5.5. The specific gravity was 1.018. Two to four white cells per high-power field were seen in the sediment. The stools were negative.

The blood nonprotein nitrogen was 20 mg. per 100 cc., the blood sugar 88 mg., and the cholesterol 186 mg. A urine-concentration test showed that the specific gravity was 1.022-1.028. There was no albumin. A phenolsulfonephthalein test was normal. The 17-ketosteroids were 8.4 mg. per 100 cc. in twenty-four hours. The test for follicle-stimulating hormone was positive for at least 6.5 mouse units per twenty-four hours. An electrocardiogram showed a normal rate of 80. The PR interval was 0.14 second. ST₁ was slightly depressed. In Lead 3, the ST segment was slightly elevated and the P and T waves were low.

An x-ray film of the chest showed a slightly enlarged heart. The left ventricle was more rounded than usual. The aorta was slightly tortuous but not dilated. The lungs were clear. An intravenous

pyelogram was negative. Numerous blood-pressure determinations gave averages of 188 systolic, 140 diastolic, while lying down, of 180 systolic, 145 diastolic, while sitting and of 192 systolic, 152 diastolic, while standing. A cold pressor test gave a blood pressure of 220 systolic, 170 diastolic.

She remained essentially the same, and on the twenty-second day a right lumbodorsal sympathectomy was performed. Postoperatively there was no striking change in the blood pressure. On the thirty-seventh day a left lumbodorsal sympathectomy was performed. The blood pressure was not affected, and she was asymptomatic until the sixth postoperative day, when she had a generalized convulsion lasting about five minutes, with associated urinary incontinence and biting of the lips. During the attack the head was turned to the right and there was considerable frothing at the mouth. Following the attack the blood pressure was 260 systolic, 170 diastolic.

Six days later she had "a second brief seizure." Four days later a lumbar puncture gave an initial pressure of 180 mm. of water, and 3 cc. of clear fluid was withdrawn. The total protein was 213 mg. per 100 cc., and there were no cells. The vomiting and headache persisted. The patient complained of inability to see. Examination of the fundi showed $\frac{4}{3}$ to 5 diopters of choking of the right disk, and 3 of the left. X-ray examination of the skull was negative. A second lumbar puncture, eight days after the previous one and performed at the height of a headache, showed an initial pressure of 310 mm.; 10 cc. of clear colorless fluid was withdrawn. A subtemporal decompression was performed. The blood pressure was 240 systolic, 190 diastolic. The blood nonprotein nitrogen was 18 mg. per 100 cc. The patient eventually improved and was discharged on the eighty-sixth hospital day.

Final admission (five days later). The patient remained well until two days before admission, when she had seven convulsive seizures and became unresponsive.

Examination showed an emaciated, stuporous girl with a left hemiplegia and a positive Babinski on the right. The decompression site was bulging. The blood pressure was 255 systolic, 175 diastolic, the temperature 102°F., the pulse 120, and the respirations 20.

The urine was acid, with a specific gravity of 1.020 and positive tests for diacetic acid and acetone; the sediment contained 1 to 5 white cells and 1 to 5 red cells per high-power field. The nonprotein nitrogen was 45 mg. per 100 cc., the carbon dioxide combining power 23.3 millimols per liter, and the chloride 100.5 milliequiv. per liter.

The patient failed to regain consciousness and died on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. PAUL D. : The pseudoarthrosis, I suppose, represents a fracture.

Apparently there was a sudden fulminating or to this illness.

The blood pressure was consistent with malignant hypertension.

"She was found to have a urinary-tract infection and was put on adequate dosage of sulfadiazine. Previously, she had had no history of kidney infection, and I wonder if this was not secondary to serious prolonged illness rather than an important primary factor.

The relation between the hemiplegia due to cerebral lesion, whatever it may have been, and blood pressure is of prime interest. I wonder which was cart and which was horse.

The hirsutism impressed me, and I looked for other manifestations along this line to indicate something like Cushing's disease, but that was not found. It may suggest adrenal hyperplasia.

The abdominal examination leaves me uncertain whether or not a tumor was present in the left flank.

The severe retinopathy might certainly have been hypertensive.

The difficulty with sight was much more marked than that usually seen in hypertensive retinopathy and suggests optic atrophy.

I was not sure what the Hoffmann sign was, and I looked it up. It is flexion of the terminal phalanx of the thumb and of the second and third phalanx of the fingers when the nails are suddenly pressed. The Oppenheim is extension of the toes when the inner side of the leg is scratched or stroked. Chaddock is positive when, on irritating the extensor malleolar skin area, the great toe extends, as in case of organic disease of the corticospinal reflex pathway it resembles the Babinski.

The laboratory findings were essentially negative. Dr. Albright told me this morning that a value of 8.4 mg. for the 17-ketosteroids is a normal finding. The electrocardiogram was normal. It looks as if aortic disease was not present, but that there may have been a little hypertensive heart disease, and an increase in the size of the left ventricle.

After the first operation "there was no striking change in the blood pressure." One does not expect a drop that early even if the result is eventually successful. The blood pressure should have been affected by the second operation, however, if the procedure was going to be beneficial. All the cases that I have seen that were successful had an early drop in blood pressure after the second operation.

The episode on the sixth postoperative day sounds like an epileptic fit.

There apparently was no deformity of the vertebrae, and the bones were not porous. The temporal decompression was evidently done to relieve pressure.

We have three chief problems: first, the cause of the hypertension; second, the relation of the hypertension to the cerebral lesion; and third, the cause of death. I do not believe that there is any good

vidence for renal etiology, for coarctation of the aorta or for subarachnoid hemorrhage, either primary or secondary. Hypertension may be found in cases with subarachnoid hemorrhage, but usually the blood pressure is normal and is not elevated much by such a hemorrhage.

I have read over the features of Cushing's syndrome, — that is, basophilic adenoma of the pituitary, — and this case does not seem to fit. The girl was not painfully obese, nor did she have striking sex changes. Also, the hypertension seems much too great. I do not recall having cases with such a high pressure brought to my attention. The adrenocortical syndrome does not fit either, that is, with tumors in the usual sites, unless Dr. Smithwick, who did this operation, removed one that we may hear about later and unless something else came from it. I know that Dr. Smithwick in his lumbodorsal splanchnic resections explores the kidneys and the ordinary sites of adrenal tumors. Could there have been a simple cortical adrenal hyperplasia, unidentifiable by gross inspection, that produced the situation found in this patient?

A rare ovarian tumor, known as arrhenoblastoma, has been noted to cause hypertension and excessive hair, without hyperglycemia or osteoporosis. But there is no evidence of that here. There was a suggestion of something in the left flank, but I cannot diagnose such a tumor on that basis.

Essential hypertension is possible even at an early age, but it must be considered as extremely rare under twenty. Some, probably considerable, evidence against such a diagnosis is the failure of bilateral lumbodorsal splanchnic resection to budge the blood pressure. In every young person with essential hypertension that I have known who has been operated on by Dr. Smithwick there has been a distinct change in the blood pressure after bilateral lumbodorsal sympathectomy. I should like a comment on that from Dr. Smithwick himself.

Finally, one must consider a brain tumor that involved, by pressure, the temporal area and motor cortex on the right and the optic nerves, with initial hemorrhage into the ventricles and spinal canal and resulting secondarily in generalized hypertension.

DR. JOHN ABBOTT: May I contribute one item that is not recorded in the history? An electroencephalogram indicated a lesion of the motor cortex, maximal in the right temporal region.

DR. WHITE: I thought from the data I had that brain tumor might be the best bet, but it is extremely rare in my experience to be asked to see anyone with hypertension of which brain tumor is the cause. Of course cerebral hemorrhage can be induced by either hypertension or brain tumor. I should like to ask the neurologic experts how much vascular hypertension can be produced by a brain tumor. I think that it is much less likely to discover in such a young person what we might find in a middle-aged or older

person — namely, cerebral vascular disease with apoplexy secondary to essential hypertension.

If it was a tumor, I do not know the type. Perhaps it was a glioma. A metastatic tumor in the brain has to be considered. I was rather intrigued by the thought that it might have been a hypernephroma; but that is very, very rare.

CLINICAL DIAGNOSIS

Hypertension.

DR. WHITE'S DIAGNOSIS

Hypertension and cerebral hemorrhage of unknown cause, perhaps due to brain tumor.

ANATOMICAL DIAGNOSES

Occlusion of orifices of renal arteries: complete (right) and partial (left).

Arteriosclerosis: left kidney, spleen, pancreas and brain.

Cardiac hypertrophy, hypertensive type.

Cerebral infarction, with secondary hemorrhage: right lenticular nucleus.

Bronchopneumonia, terminal.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The striking finding was in the orifices of the renal arteries in the aorta. In place of the orifice of the right renal artery we were able to find only a dimpling of the intima; the proximal 6 mm. of the vessel was narrowed by fibrous tissue to a mere pinpoint, if open at all (Fig. 1). Then the vessel abruptly became patent, with a circumference of about 10 mm., the point of dilatation being where the suprarenal branch was given off. The orifice of the left renal artery, although not occluded by fibrous tissue like the right, was markedly constricted to about 1 mm. in diameter for a distance of about 3 mm.; it then dilated to about 15 mm. in circumference. Distal to the occlusion on the right and within the narrowed portion on the left were small, fairly recent thrombi. We have, therefore, a situation in man analogous to the Goldblatt dog; in which hypertension is produced by clamping both renal arteries. I am at a loss to explain the pathogenesis of this process. Microscopic examination of sections through the points of occlusion and narrowing show merely old organized fibrous tissue, which may at one time have been thrombi superimposed on an arteriosclerotic lesion.

Another interesting finding was the presence of a moderate degree of arteriosclerosis in the left kidney and none in the right. This is also somewhat analogous to the rare form of hypertension due to a unilateral ischemic kidney, in which arteriolar changes are found only in the opposite kidney.

The heart was enlarged, weighing 300 gm.

The changes in the brain were those of an infarct with secondary hemorrhage, at least that is what Dr. Kubik believes it to be rather than the result of cerebral hemorrhage. There was severe diffuse vascular disease in the small vessels of the brain.

DR. REGINALD H. SMITHWICK: We now have several hundred cases of hypertension treated surgically, and Dr. Castleman has dipped into this

adrenal glands. As you can see, this case here about as close a counterpart of the Goldblatt syndrome in dogs as one could possibly see in a human being, and as I have said, is the only case in our experience. The only thing that was missing was actual presence of the clamp itself.

DR. WHITE: What did you think after the operation failed to bring down the pressure? You thought that something was wrong?

FIGURE 1. Schematic Drawing of Arterial Supply of Kidneys Showing Occlusion of the Orifices of the Renal Arteries.

group and selected two of the rarest for discussion today. The second case is the only example of this sort in the series, and I have never come across such a case in the literature.

DR. WHITE: Did you find this at operation?

DR. SMITHWICK: No, because the occlusions were practically within the aorta. The operative field permits careful examination of most of the renal artery, the kidney and the adrenal gland; the extra-aortic part of the renal artery, however, did not impress me as being particularly remarkable. Incidentally, it is extremely important, in any operation for hypertension, to include exploration of the kidneys and

DR. SMITHWICK: Yes, because that was no I anticipated.

DR. WHITE: What percentage do you bring at that age?

DR. SMITHWICK: Between 80 and 90 per cent.

DR. WHITE: Dr. Ayer, how often do you see hypertension with brain tumor?

DR. JAMES B. AYER: We rarely see as much tension as this patient showed.

DR. WHITE: The association of hypertension and brain tumor is commonly referred to in text but I wonder how often you actually encounter

DR. AYER: Practically never.

SUBSCRIPTION TERMS: \$6.00 per year in advance, postage paid, for the United States (medical students, \$3.50 per year); Canada, \$7.04 per year (Boston funds); \$8.52 per year for all foreign countries belonging to the Postal Union.

MATERIAL for early publication should be received not later than noon on Friday.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts

PATULIN AND THE COMMON COLD

"What's good for a cold?" This question has always been certain to embarrass physicians since they, too, would be glad to have the answer to that question and employ it whenever they were troubled by this common malady. When a remedy for the common cold is offered, and particularly if that remedy happens to be in the form of an agent related to such a widely hailed and effective substance as penicillin, it is easy to understand why physicians and the lay public are both interested and intrigued. Such a remedy is discussed in a recent issue of the *Lancet*,* which contains a report on the use of patulin

*Ralswiek, H., and others. Patulin in common cold. Collaborative research on derivative of *Penicillium patulum* Bainier. *Lancet* 2:625-635, 1943.

in the common cold. This study is the result of a collaborative research by a group of biochemists in the London School of Tropical Medicine and Hygiene and by a number of clinical investigators.

Patulin is the name given to a substance obtained as a metabolic product from the filtrate of cultures of *Penicillium patulum*. This new agent is of great interest for several reasons. The active substance has been isolated and crystallized, and its chemical structure has been defined. It happens to be a relatively simple chemical compound. The yields of this material from cultures are relatively large as compared with those of similar products, such as penicillin. Furthermore, it seems to be equally effective against both gram-positive and gram-negative bacteria. Against the gram-positive organisms it is less effective than penicillin, whereas against the gram-negative ones it is more effective. The substance is quite stable in the crystalline form, but some changes do take place if an aqueous solution is permitted to stand at room temperature for several days. It is not inactivated by either serum or pus.

On the other hand, the results of toxicity experiments indicate that this drug has a much narrower range of safety between concentrations that are effective and those that are toxic. In acute toxicity experiments the average lethal dose was 0.5 mg. for a 20-gm. mouse. This amount given either intravenously or subcutaneously produced death accompanied by widespread capillary damage in the liver, spleen and kidneys as well as pulmonary hemorrhages and edema. Convulsions occurred soon after the material was given intravenously. Similar toxicity was observed in rabbits with even smaller amounts. When injected subcutaneously in animals, it produced local necrosis. The substance was also toxic to leukocytes. It was found that phagocytosis of killed staphylococci by leukocytes was unaffected by a dilution of 1:8000 but was completely inhibited when a dilution of 1:2000 was used.

The reported clinical trials concern only its use in the common cold, which is usually considered to be a virus disease. Cases having a protracted course are usually those in which the virus infection is followed by a bacterial complication of the nose,

pharynx or accessory nasal sinuses. Such complications are the result of infection with the common respiratory pathogens, and these appear to be amenable to the use of patulin. The method used in the clinical trials consisted of either spraying the nose and throat, douching the nose, or sniffing. It was used in a buffered aqueous solution and administered every four hours in dilutions of 1:5000 to 1:20,000. The more concentrated solution produced local irritation, some patients complaining of transitory stinging and others of a profuse nasal discharge for about half an hour. This was not noted with the more dilute solutions. Apparently no other ill effects were observed.

Interestingly enough, the first clinical trial was by Dr. W. E. Gye, director of the Imperial Cancer Research Fund Laboratory, who was given a supply of the material for an experimental study of its effect in cancer. Dr. Gye was suffering from a severe cold at the time that he received the substance so he made up a solution, sniffed it and was rapidly relieved of his symptoms. He then supplied some of the material to colleagues, who likewise felt that the chief symptoms of their colds were rapidly alleviated. Dr. Gye's note makes no mention of the effect of this substance in experimental cancer.

The material was then supplied to Surgeon Commander Hopkins, of the Royal Navy, who reported on the antibacterial efficacy of the drug as well as on its toxicity in animals. He also set up two types of clinical study: a control series among officers and enlisted men who volunteered for treatment and an evaluation of the clinical effects based on careful notes by colleagues and friends. The cases were carefully selected to exclude persons who already had evidence of complicating infections and also to eliminate cases of clinical influenza. The results of the control study showed that 58 per cent of 95 persons receiving patulin in various concentrations during the first few days of an uncomplicated cold were "cured" within forty-eight hours. In 85 control patients who received a solution of the buffer without patulin less than 10 per cent were benefited within this same period. The data were reviewed by Major Greenwood, a professor of epidemiology and vital statistics, and were found to be statistically significant. They calculated that the probability of

these results being a matter of chance was only three in ten thousand. A smaller number of cases diagnosed clinically as influenza were treated with beneficial effects. Interestingly enough, in those patients treated for the common cold who previously had had frequent colds that were followed by sinusitis, only temporary improvement was noted and sinusitis was not prevented when patulin was used presumably because the drug did not reach the infected areas.

Most of the physicians who were asked to use the material personally and to make careful notes of the results were quite enthusiastic. They stated that their symptoms were rapidly alleviated. On the other hand, this group also contained a number in whom symptoms of sinusitis were not prevented. In many of the subjects who responded favorably the acute symptoms often completely disappeared within a few hours; many, however, had a recurrence of discharge from and stuffiness of the nasal passages after a few hours and this was repeated several times before they were completely relieved. No effects were noted beyond the local irritation when the larger doses were used.

In view of the fact that the most serious types of complication of the common cold were not prevented, further elucidation of the mechanism whereby the results were obtained seems necessary. Although extensive clinical trials are indicated, there is little prospect of any large supply being immediately available. Furthermore, a great deal more should be known about the pharmacological actions of the drug in human cases as well as in animals before any widespread use is permitted.

The fact that the chemical formula of the substance is known opens a wide field for further study. First of all, one may anticipate that it will be possible to synthesize this material. When sufficient materials are thus made available, one may anticipate numerous modifications of the chemical structure in the hope of reducing its toxicity and increasing its effectiveness, as has been true of the sulfonamides. In addition, the findings seem to justify extensive research on antibacterial substances from molds and other higher bacteria. One may expect much progress in this field in the next few years.

HOLMES AS A PSYCHIATRIST

The medical aspects of Holmes's career are being re-examined and re-evaluated. His place in American literature is secure, but many are asking what about his niche in American medicine? Did he, except for his outstanding contribution in 1843 to preventive medicine, the paper "On the Contagiousness of Puerperal Fever," exert any considerable influence on the trend of medical thought or leave buried in his writings material not fully appreciated at the time of its writing, or since? Undoubtedly the stamp of Holmes's dynamic character left an impression on a generation or more of the medical students who attended his anatomical lectures. He gave an impetus, moreover, to the public demonstration of the administration of ether by coining the term "anesthesia," stimulated research with the aid of the microscope and used his vast influence in 1875 to re-establish the Boston Medical Library for his generation and for posterity. These are, however, as time has listed them, minor contributions. What else did Holmes add to the medical scene? What about the "medicated novels," and Holmes as a psychiatrist?

Little attention has been paid to Holmes's interests in mental aberration or to Holmes as a clinical psychiatrist. It is now realized, thanks to the researches of Oberndorf,* that Holmes was long a profound student of mental disease and that he had pronounced and advanced ideas on mental mechanisms. Possibly hesitant about presenting his thoughts before his medical colleagues, or at least doubtful about their acceptance in the form of a medical paper, he chose the medium of the novel to bring his opinions before the public. Neither *Elsie Venner* (1859) nor *The Guardian Angel* (1867) was a literary product of excellent quality when compared with contemporary works of Poe, Thackeray and Hawthorne. But they were studies of the abnormal mind, and simple though the stories are, both books give us an insight into Holmes's profound psychiatric understanding. His doctors, moreover, combine, as noted by Oberndorf, "those qualities so desirable in every physician but indispensable in a psychiatrist — namely, patience, forbearance,

tolerance, equanimity, accurate observation of the patient's actions and utterances, and unremitting consideration for the patient's psychological and environmental handicaps."

Following the novels, Holmes became so engrossed in the theme of the social significance of mental deviation that he chose this subject for his address to the Phi Beta Kappa Society at Harvard in 1871. "Mechanism in Thought and Morals," as the paper was called, was withheld from publication for more than twenty years, and only after careful revision, expansion and annotation had taken place, did Holmes allow it to appear in print, hidden in *Pages from an Old Volume of Life* (1892). There, this address, with its modern flavor and psychoanalytical leanings, has been allowed to rest nearly unnoticed. In this essay will be found opinions strangely similar to those so reluctantly accepted by the medical profession after they were re-emphasized by Freud forty years later. In the brain, Holmes considered, there persists a material record of thought; and secondly, this transmissible record is not at all times available to the person for the control of his actions. Are these ideas not the "indestructibility of infantile thought and impressions" and the "importance and influence of unconscious mentation" — the foundation stones of Freud's psychoanalytic structure? At least Oberndorf thinks so, and his book makes a strong case in Holmes's favor. Except for a pleasant whimsicality, so characteristic of Holmes, the following passage from his address might well have been written by Freud in 1910:

There are thoughts that never emerge into consciousness, which yet make their influence felt among the perceptible mental currents, just as the unseen planets sway the movements of those which are watched and mapped by the astronomer. Old prejudices, that are ashamed to confess themselves, nudge our talking thought to utter their magisterial veto. In hours of languor, as Mr. Lecky has remarked, the beliefs and fancies of obsolete conditions are apt to take advantage of us. We know very little of the contents of our minds until some sudden jar brings out the old stockings full of gold, and all the hoards that have hid away in holes and crannies.

MEDICAL EPONYM

SCHEUERMANN'S DISEASE

Dr. Holger Werfel Scheuermann (b. 1877), of Copenhagen, Denmark, described "Kyfosis dorsalis juvenilis [Juvenile dorsal kyphosis]" in the *Ugeskrift*

*Oberndorf, C. P. *The Psychiatric Novels of Oliver Wendell Holmes*. New York: Columbia University Press, 1943.

pharynx or accessory nasal sinuses. Such complications are the result of infection with the common respiratory pathogens, and these appear to be amenable to the use of patulin. The method used in the clinical trials consisted of either spraying the nose and throat, douching the nose, or sniffing. It was used in a buffered aqueous solution and administered every four hours in dilutions of 1:5000 to 1:20,000. for laeger (82: 385-393, 1920). A German summary may be found in *Zeitschrift für Orthopädie und ihre Grenzgebiete* (41:305, 1921), and an English summary appears in *Acta Chirurgica Scandinavica* (54: 29, 1922). A portion of the latter follows:

Among spinal deviations at the age of puberty there are many cases which clinically and morphologically form a complete group. These are real fixed kyphoses in columna dorsalis or dorsolumbalis in arcuate form. . . .

The cause . . . lies, in my opinion, in the morbid condition of the growing-area between the epiphysis and corpus. . . .

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

EGAN — John J. Egan, M.D., of Gloucester, died January 22. He was in his seventy-fourth year.

Dr. Egan received his degree from Harvard Medical School in 1894. He was a member of the Massachusetts Medical Society and the American Medical Association.

Three sons and a daughter survive.

LOWENTHAL — Karl Lowenthal, M.D., of Fall River, died January 16. He was in his fifty-second year.

Dr. Lowenthal received his degree from Albert-Ludwigs-Universität Medizinische Fakultät, Freiburg, Baden, in 1915. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives.

STEIN — Albert Stein, M.D., of Thompsonville, Connecticut, died December 5, 1942. He was in his fiftieth year.

Dr. Stein received his degree from the University of Maryland School of Medicine and College of Physicians and Surgeons in 1917. He was a member of the Massachusetts Medical Society and the American Medical Association.

WAR ACTIVITIES

INDUSTRIAL MEDICINE

ALLOWABLE CONCENTRATIONS OF TOXIC DUSTS AND GASES

At a recent meeting of the committee of the American Standards Association concerned with approval of allowable concentrations of toxic dusts and gases, it was reported that six standards had been approved during the present calendar year, and that altogether twelve standards had been promulgated under the auspices of the committee since its reorganization two years ago.

The standards now being considered are on methanol, styrene monomer, formaldehyde, trichlorethylene and acrylonitrile. A standard on toluene has been approved and published. The proposed standards for oxides of nitrogen approved by the committee are now being processed through the Safety Code Correlating Committee.

Considerable discussion was given to the preparation of a standard for exposure to silica dust. It was finally decided to prepare a standard that would take into consideration the data now available for threshold limits for various industrial dusts with a silica content. The consensus was that no single maximum allowable concentration could be developed in view of the fact that no two dusts containing silica have the same effect on health, even when the silica content is the same.

The chairman was authorized to appoint subcommittees to consider the following standards: methyl chloride, which is now being used in place of Freon as a refrigerant; hydrofluoric acid, fluorine and fluorides; and radon, gamma rays and x-rays.

It was agreed by the committee that the recently circularized code on carbon tetrachloride should be rewritten, with a footnote to the effect that subjective symptoms may

be experienced when workers are exposed to concentrations lower than 100 parts per million and, for that reason, that attempts should be made to achieve concentrations lower than the standard recommended.

MISCELLANY

AMERICAN COLLEGE OF SURGEONS

Twenty-two cities throughout the United States and Canada have been selected by the American College of Surgeons as headquarters for one-day "war sessions" to be held in March and April. Advancements in military medicine and developments in civilian medical research and practice under the spur of the war emergency will be presented by authorities representing governmental agencies and by civilian physicians and surgeons. The meetings will be open to the profession at large, including medical officers of the Army and the Navy, residents, interns, medical students and executive personnel in hospitals. For the last, special hospital conferences, to be held simultaneously with the scientific sessions, are being arranged.

Each meeting will open at 8:30 a.m. with the showing of official Army and Navy films on medical and surgical subjects, such as evacuation of the wounded, fractures, bomb blast, burns and treatment of wounds. From 9:30 to 11:30, Army and Navy representatives who have been on active duty abroad will report; from 11:30 to noon, representatives of the United States Public Health Service will report on measures for the control of endemic and epidemic diseases. Current problems of the Procurement and Assignment Service will be presented by a representative at the luncheon conference from 12:15 to 2:00 o'clock. Between 2:15 and 5:00 scientific presentations by medical members of the armed forces and of the Veterans Administration and by civilian members of the medical profession, including someone engaged in the practice of industrial medicine, will be made. From 5:00 to 5:30 the need for protective service in time of war will be presented by a representative of the Office of Civilian Defense. The concluding session will be a dinner meeting and open forum with all participants in the day's program as the panel of experts to lead discussion of any and all subjects presented during the day, together with other problems of interest to the medical and hospital professions. The motion-picture showing, Public Health Service session, luncheon conference, Civilian Defense program and dinner meeting will be attended by both the medical and hospital groups. The hospital representatives will discuss wartime hospital problems and how they are being solved from 9:30 to 11:30, and will hold a round-table conference on "Wartime Hospital Service" from 2:15 to 5:00.

The preliminary schedule for the meetings is as follows:

DATE	CITY	STATES AND PROVINCES
February 28	Winnipeg	Manitoba, Saskatchewan
March 2	Minneapolis	Minnesota, North Dakota, South Dakota
March 4	Des Moines	Iowa, Nebraska, Missouri
March 6	Chicago	Illinois, Wisconsin
March 8	Cincinnati	Ohio, Kentucky, Indiana, West Virginia
March 10	Detroit	Michigan
March 13	Rochester	New York State
March 15	Toronto	Ontario
March 17	Montreal	Quebec, New Brunswick, Nova Scotia, Prince Edward Island
March 20	Springfield	Newfoundland, Massachusetts, Maine, New Hampshire, Vermont, Rhode Island, Connecticut
March 22	Philadelphia	Pennsylvania, New Jersey, Delaware
March 24	Baltimore	Maryland, District of Columbia, Virginia
March 27	Jacksonville	Florida, Georgia, North Carolina
March 29	Jackson	Eastern Tennessee, Mississippi, Louisiana, Western Tennessee, Alabama
April 1	San Antonio	Texas, New Mexico, Mexico
April 4	Tulsa	Oklahoma, Kansas, Arkansas
April 7	Denver	Colorado, Wyoming, Western Nebraska
April 11	Salt Lake City	Utah, Idaho
April 14	Spokane	Washington, Northern Idaho
April 18	Vancouver	Oregon, Montana
April 24	San Francisco	British Columbia, Alberta
April 27	Los Angeles	Northern California, Nevada, Southern California, Arizona

(Books Received on page ix)

ied the professional donors but also could call donors at any time when the supply of blood a particular group was too low. Soon this side of e business increased because one third of the trans- sions were among the private or semiprivate pa- ents. Because of available voluntary donors, the tire fund was never used; recently, because of a ortage of professional donors owing to the de- ands of war work, it has also grown so that there now about \$5000 on hand. This fund is most use- l for patients who require fresh blood; they send their voluntary donors at any time, and a pro- sional donor is sent for at the time the trans- sions are requested, fresh blood being furnished no extra charge. To keep up the supply of Rh- oods, these are purchased from the donor list or c Blood Grouping Laboratory (Children's Hos- tal, Boston). Before holidays or at any time when tra bloods of a given group are needed, pro- sional donors are sent for and a supply is laid in.

SYSTEM OF CREDITS AND DEBITS

Most fundamental to adequate service in a blood ink is a constant stream of donors well in excess of eds. Many banks have run into serious difficulties cause of neglecting this simple truth. For each hos- tal the problem is different. Prior to the establish- ent of our bank, we had plenty of available volun- ry donors, so that no shortage was anticipated beginning operation.

SYSTEM OF PATIENTS' CREDITS

To keep up a larger volume of deposits than of thdrawals, it was requested that for each trans- sion two or three bloods be deposited in the bank. urthermore, no blood is allowed to be issued to a tient who has no deposits on hand unless there is guarantee of cash replacement. To enforce this, the patient has no credit, permission for trans- sion must be obtained from one of the hospital rectors. The directors are moderately severe in forcing this provision, with the result that neither e hospital staff nor the patients do much side- epping of obligations. The necessity for this is vious. In the first place, the patients' families rely replace bloods already received; in the second ace, it is difficult for a blood-bank nurse to refuse issue blood to a physician, whereas a director can adily do so if he thinks that little or no effort has en made to obtain donors. In worthy cases where ere is no credit, the director's permission is given r his signature on the requisition. This permission given freely, and by telephone in emergencies. To ep track of the patient's credit, a card file is main- ined in the bank, listing for each patient the num- r of donations of usable blood and the number of thdrawals for actual use. Blood withdrawn from e bank but not given, as happens occasionally, is a rule, charged to the patient, although in certain

cases the bank has accepted the loss. On the wards, the intern staff follows the patient's debit and credit on a deposit and withdrawal form marked with a rubber stamp. All this is complicated, but it actually saves both labor and disputes and provides a wise safeguard against profligate withdrawals.

Bloods do not expire with the passage of time on a patient's credit slip unless the patient leaves the hospital for a month or so. This is only fair, since blood costs the patient money and takes time and trouble to obtain. The blood bank loses nothing by permitting this or by relaxing its policy of maintain- ing credit beyond a month of absence in isolated cases. As a rule, the volume of blood coming in amply covers withdrawals, regardless of when the initial deposits were made.

SERVICE CREDIT

The record of credit or debit of the different serv- ices or divisions of the hospital is to the blood bank what a balance sheet is to commercial banks with this fundamental difference: Good service can be pro- vided only if there are ample amounts of four forms of currency, — that is, the four blood groups, — *whereas commercial banks deal with only one form.* Furthermore, two of the groups, Types B and AB, are rare. To be sure, to have enough blood on hand to care for a bleeding peptic ulcer in a Type AB patient a minimum of sixty bloods of all types must be on hand; in actual practice a minimum of eighty to one hundred is generally safer. Although there is no hesitation in using a carefully cross-matched universal donor's blood from a repeatedly typed professional donor in an emergency, or in switching to the original type after a fresh blood has been taken from a patient for cross-matching, it is still pre- ferred to administer a blood of the same group as the recipient's and an effort is therefore made to keep bloods as close to the one-hundred mark as possible.

In keeping to this standard, which is often difficult, the system of service credit is regarded as the most important factor. Under this system, the actual number of usable deposits made to the credit of a service — that is, by the donors for pa- tients on a service — is recorded on a blackboard, and from this are subtracted the bloods used by that service or belonging to it and expiring unused at the end of seven days. No credit is given for a blood of small quantity or with a positive serologic test or one that is considered otherwise unusable. This credit is much more real than the patient credit, for it represents actual blood on hand, less, of course, blood given out to the patients paying cash and for whom professional donors have not yet been purchased. Thus, when a blood is deposited for one of the surgical services but is actually given to a private patient who pays for it, it is listed to the credit of the surgical service long after it has ac- tually been used; at the same time the debit for this

blood is listed in the debit column under "professional donors." On each occasion when professional donors are sent for, the bloods used are subtracted from the debit column, the service not losing credit until a blood is actually given to its patient. This system is obviously open to criticism on the ground that the service credits of all services minus the debit for professional donors not yet sent for could readily equal zero and there would be no blood in the bank. To prevent this from occurring, a careful check is kept of bloods of all groups actually in the bank with an eye to preventing depletion. The number of bloods has on occasion gone as low as eight and as high as one hundred and thirty, but as a rule an average of sixty bloods is maintained, which cares for sixteen transfusions a day.

The enforcement of this system is, however, no less important than is the understanding of its functions. A credit is insisted on at all times. Although the issuance of bloods to a patient with credit is continued when the service has none, — and out of all fairness to patients, there could be no other course, — the responsibility for the debit is placed on the head intern or resident of the service involved. He is warned by the nurse in charge of the bank when his credit is low. How low it is depends on the volume of blood used, for the general surgical services, a low level is considered to be 6000 cc., because sick patients may exhaust this supply in a few days, whereas for the Dermatological Service a credit above 1000 cc. is considered high. A debit calls for admonition from the bank director to the resident. A lack of response is usually followed by an appeal to the chief of service by the bank director, and as a last resort, the director of the hospital is informed of the situation. It is rare that any person above the house staff has to be appealed to. This is only true because the co-operation of the chiefs of service and the support of the hospital director can be relied on. This system will only work in well-co-ordinated private hospitals.

When patients are transferred from one service to another, their credit goes with them. This works a hardship on the medical services but is on the whole fair, because the preoperative use of blood is equaled or exceeded by its operative or postoperative use; if credits remained stationary, the surgical services would often be unfairly in debt. Expiration of blood, causing a debit, is a great hardship; unfortunately, the only method of compensating for it is to maintain a great excess of donors over transfusions (high service credit). The benefit of expiration is that it means plenty of plasma for therapeutic or research purposes.

CARE OF DONORS

It is the responsibility of the doctor in charge of a patient to send for donors well in advance of the time needed. This responsibility sometimes de-

volves on a nurse at the Information Desk. This means that the patient's relatives frequently receive a slip of paper telling of banking hours and the rules about diseases and the taking of alcohol and food. If they are infrequent visitors to the hospital, they receive a telephone call, telegram or letter. The bank is open five afternoons a week, two evenings until 7 p.m., and on Saturday mornings. Tuesday afternoon is the only time for receiving donors by appointment, the reason being that many speak too little English and that others come from too long distances to keep exact dates. An attempt is made to receive donors for private patients or volunteer donors on Tuesday afternoons. Evenings are popular for war workers. Saturday afternoon and Sunday would be popular times for donors, but since attendance of the entire bank staff would be required they are avoided.

An effort is made to have donors looked after as far as possible by a volunteer worker, who makes out their cards, supervises their signing a release (these are needed in most states), and provides them with magazines and so forth while they are waiting. A history regarding contagious, debilitating and allergic diseases is taken, also the hour of last eating, alcohol ingestion, and the time of the last donation of blood. The history-taking and a brief physical examination, including the heart, the respiratory system, the blood pressure, the lymph nodes and, for males, the genitalia, are done by an intern. A blood smear is made and the hemoglobin and the temperature are determined by a technician. Donors are rejected if they have had transmissible, recent or debilitating diseases, are allergic, have eaten within the last four hours, or have taken alcohol within the last twelve hours. Abnormal blood smears and positive serologic reactions are cause for the discarding of blood. The main objection to recent eating lies in the elements of the donor's diet to which the patient is sensitive. This is also true of certain alcoholic beverages, but on the whole the main objection to the donor who has been drinking is lack of co-operation and frequent vasomotor collapse after phlebotomy. Donors of eighteen to seventy years of age are accepted outright, those under twenty-one years only with the permission of their families, and those over fifty-five only if in excellent condition, particularly so far as cardiac and peripheral vascular systems are concerned. Women weighing less than 100 pounds are usually rejected. On request of their physicians, patients with polycythemia, hypertension or decompensation are accepted as donors, but the blood of those with polycythemia is usually discarded, since it is too viscous to run freely. In a year's operation, between 16 and 20 per cent of donors were rejected on the ground that the giving of blood would be harmful to them or, more often, that their blood would be of poor quality or harmful to the patients.

When a donor is ready for phlebotomy, the outer clothing is removed and a clean gown and mask are put on. The donor is led into the bleeding room, where curtains are drawn between the tables so that he sees no blood being drawn. We do not agree with certain other bleeding centers that the observation of others being bled exerts no psychological effect or that, if it does, the effect is a beneficial one. We believe that the contrary is true, and our rate of syncope during phlebotomy is almost negligible. After termination of the procedure, the donor lies for five to ten minutes on the table, which is cushioned and soft; he is then escorted to a bed on low shock blocks in the recovery section, where milk,

tubing, which are washed with a high-speed water jet and soaked in N/10 sodium hydroxide, followed by thorough rinsing. The nurses who use the needles sharpen them on an electric grindstone, an important point in all intravenous work. The system of blood collection is a closed one operating by gravity instead of a vacuum — that is, there is an outlet on the head of the flask to permit the exit of air. A cotton air filter is inserted in the outlet to prevent contamination of the set by the entrance of air as the bottle cools after sterilization, or as air goes in and out with changes of room temperature and atmosphere pressure. These sets work well and are simple to operate. If the blood flow is slow, an

FIGURE 1. *The Blood-Withdrawing Set with Filter in Place.*

peanut butter and crackers are given. After a minimum of twenty minutes' rest, or longer if there is any feeling of faintness, the donor dresses and leaves the hospital. There have been rare cases of collapse after leaving the bank, but almost without exception these have occurred among donors who failed to follow the rules. Donors are sent cards giving their blood group and the date of donation, with room for more dates to be added.

THE TAKING OF BLOOD

The bleeding of a donor is regarded as an operating-room procedure and is carried out with complete sterile technic throughout. Under this system, the number of contaminated plasmas has been extremely low, so that it seems to be justified. The entire recipient set is autoclaved in heavy wrappings and is generally used within forty-eight hours of preparation. Great care is taken to clean all apparatus immediately after use, particularly needles and

Abbott suction bulb may be attached to the filter. Sixty centimeters of a 4 per cent solution of sodium citrate is used as an anticoagulant. The unnecessarily large amount is advantageous in preventing clots toward the end of the procedure or if more than 500 cc. of blood has inadvertently been drawn. This procedure has not increased hemolysis. Bacteriologic culture medium is inserted in the sets from time to time to check the effectiveness of sterilization.

The nurse taking the blood wears operating-room clothes and is gowned, scrubbed and gloved. The donor's arm is prepared for her by a nonsterile assistant with ether and then iodine. The needle (a No. 14 steel cannula with a glass adapter) is inserted through a novocain wheal without incision. The adapter gives prompt visual evidence of venipuncture. Only two tries are made on a donor, one on each arm, unless he is insistent on further ones. At the termination of the procedure, the tubing is clamped immediately above the flask on both the intake and outlet and cut. Blood for a Wassermann

test, blood grouping or determining the Rh factor is collected in two test tubes. The blood in the flask is agitated throughout the procedure and for half a minute afterward, since the anticoagulant is extremely diluted at the end, requiring extra shaking. The blood is allowed to cool to room temperature for half an hour before refrigerating, since slow cooling lessens hemolysis. The flask and its test tubes are labeled with the donor's number before they leave his side.

BLOOD STORAGE

Prior to the Wassermann report and the completion of grouping, bloods are stored by number in the

for type by letter, by color and by compartment; so also are the donors' cards. The bank book record acts as a check.

The temperature of the refrigerators and bottle coolers is kept at about 39°F. by means of thermostatic control. Prevention of a wide variation in temperature is carried out through the medium of thermometer dials on the outside of the boxes and an electric alarm system connected to the Maintenance Department, where there is someone on duty night and day. The compressors are set apart from the refrigerators to prevent agitation.

After a whole blood has reached the seven-day expiration date, it is placed in another refrigerator

FIGURE 2. The Bottle Coolers Used for Blood Storage.

laboratory refrigerator. As soon as they are ready, they are tagged with labels of different colors for the different groups and marked with the date, the donor's name and number, the Wassermann reaction and the name of the person who did the typing. They are placed in separate compartments in the bottle coolers, which are marked and colored similarly to their tags — O, A, B and AB, respectively. The donor's card, after it has been stamped to show the blood type, the Rh factor and the initials of the persons doing the grouping, is filed in a box colored and labeled similarly to the refrigerator, the cards for the oldest bloods being at the front of the box. Furthermore, this and all other information, including the person and service for whom the blood was given, is recorded in the bank book. This is an elaborate system, but an almost foolproof one so far as errors are concerned — donors' bloods are clearly separated and marked

for conversion into plasma. The donors' cards and the bottle-tags are filed after the expiration dates and disposal of the bloods have been recorded on them.

SYSTEM OF BLOOD GROUPING AND CROSS-MATCHING

The hospital changed from the Moss to the International system of blood-type nomenclature with the opening of the bank. At the same time, there was inaugurated a careful system of double checking of all groupings and cross-matchings by having each checked by a different person. This is helpful with difficult typings and avoids the mechanical errors of using wrong test tubes and so forth. Type O, A and B testing serums are used, each one being a pooled serum obtained from three high-titer donors. The blood cells to be tested are prepared in a 2 per cent saline suspension prior to being intro-

duced into the known serums on a slide. Lecithin is placed on one slide for each grouping to prevent rouleau formation, twenty minutes in a Petri dish — to prevent evaporation — being the time required for maximum agglutination; all slides are then read under a microscope. In the rare cases in which a very sick patient or one who has had a large amount of sulfonamides is difficult to group, an incubated cross-matching is done with a thoroughly well-known — usually, professional — universal donor. In not only insisting on the system of double checking all cross-matchings and groupings but in having them done by the bank staff in so far as possible, a great

Grouping Laboratory or, more rarely, Dr. Philip Levine, of Newark, New Jersey, and with it all donors are tested. A test is also done with all patients requiring multiple transfusions or having a history of reactions, miscarriages and so forth. Dr. Levine's^{1,2} method is employed for these determinations. Cross-matchings are frequently incubated for an hour, particularly if patients have had severe reactions from Rh+ blood although positive themselves, or if they are first tested after receiving several transfusions. The charges for Rh testing are \$2, \$3 or \$4 for ward, semiprivate and private patients, respectively. An average of twenty testings

measure of safety is provided, for diversification of responsibility carries the procedures into unskilled and often careless hands. An intern must have seen severe reactions in addition to possessing some knowledge of subgroups, cold agglutinins and so forth, to be able to conduct himself adequately in a blood-grouping laboratory. This is why medical students are trained to do the work at night, their work being checked by someone high up on the service — a person of known ability certified by the bank. When staff members are not present, in place of grouping and matching of the patient's blood in an emergency late at night a carefully cross-matched blood from an Rh— universal donor is used. In an extreme emergency brooking no delay, a known universal Rh— blood can be given out without cross-matching with some degree of safety. This is practically never done, since cross-matching or the use of liquid plasma is preferred for these cases.

High-titer Rh-testing serum of high specificity and stability is purchased from either the Blood

are performed each day, excluding Sundays and holidays.

PREPARATION AND STORAGE OF PLASMA

Ninety-five per cent of the plasma is drawn from bloods beyond the seven-day expiration date, and 5 per cent of it from volunteer donations. The plasma is pooled whenever there is sufficient blood on hand to do so, usually two or three times a week. The centrifuge is useful only with bloods under three days old; after that time, the cells are too fragile to withstand the 20°F. rise in temperature and concomitant agitation of fifteen minutes of spinning, which causes over one third of the bloods to show some degree of hemolysis. On certain occasions, as with the large influx of voluntary donors after the Coconut Grove fire, the yield was increased from 70 units of plasma per one hundred flasks of whole blood to 95 units by centrifuging twenty-four-hour-old blood. To make a pool, blood is selected from

all groups if possible, and never from Group O or A alone.

Prior to pooling, the air in the plasma room is sterilized by two hours of ultraviolet radiation, after which there is as little commotion and introduction of outside air as possible. The pooling of plasma is carried out as a completely sterile procedure with the workers capped, masked and in clean clothes. The operator prepares as for an operation, wearing a sterile gown and gloves. The supernatant plasma is drawn off by a needle inserted through the tubing on the bottle top, which has been previously sterilized by soaking for twenty minutes in 1 to 1000

culturing. This saves one motion and makes for one less introduction of a needle through the flask top.

Two of the culture tubes stand for a week at room temperature and two in an incubator. If two or more are contaminated, the entire pool is discarded. If one is contaminated, reculturing is done; if there is no growth the pool is used, on the theory that the original culture tube became contaminated; if there is growth it is discarded. The use of separate needles for each flask of blood or plasma, the keeping of all apparatus covered when not in use and rigid rules of preparation of sets and bottle tops (the former are autoclaved), reduces contamination.

FIGURE 4. Plasma Storage Box.

The section on the left is maintained at -30°F. for quick-freezing purposes.

solution of mercury bichloride. The needle is connected to a 2000-cc. pooling flask from which the air has been evacuated. As the plasma is drawn off, it is replaced by room air through a sterile air filter. When the pooling flask is full, it is agitated and can then be cultured immediately, or it may be left undisturbed for a few days and then cultured.

Culturing, carried out according to the rules of the Office of Civilian Defense,³ is done by inserting 10 cc. of plasma deep in each of four test tubes containing 20 cc. of the aerobic-anaerobic Brewer's medium (thioglycolate broth). The pool is then drawn off into plasma flasks with a fresh needle, after which the cap and needle are removed and a permanent metal cap is put in place. The flasks contain either 250 cc. of normal saline solution or 50 cc. of 50 per cent glucose solution, freshly prepared and autoclaved. They are usually frozen immediately at -30°F. to reduce fibrin and fibrinogen-clot formation, and are stored at -10°F. or kept at room temperature. As a rule, the plasma is drawn from the pooling flasks into the final containers, a residual being left at room temperature for a day before

It has been found that connecting water suction to the flask, if the vacuum is exhausted, leads to air leaks in the connections of the set. This suction method was instituted just before the ultraviolet lights were installed, and immediately four pools of plasma were found to be contaminated. On using the lights and changing nothing else in the technic this contamination ceased. The studies on the effect of ultraviolet radiation in reducing the bacteria in room air are not complete. Exclusive of these four pools, the percentage of contamination in the making of over twelve hundred flasks of plasma is under three per cent.

We consider a plasma diluent advantageous because it cuts down on fibrin and fibrinogen-clot formation and permits much better flowing through both the filter and needle, since plasma is viscous. It also helps to prevent agglutination of the recipients' blood cells by the action of powerful anti-A or anti-B agglutinins in the plasma. Saline solution is the better of the two diluents for mechanical reasons, but may be dangerous, because of an overdosage of salt, if more than six transfusions of

plasma so diluted are given in twenty-four hours. No mercurial preservative is used because in sterile plasma no antiseptic is necessary, because the preservatives now advocated (except sulfathiazole) are poor bactericidal or even bacteriostatic agents, and because there is danger of mercurial damage to the kidneys in the use of large volumes of plasma so treated. This damage has been proved to exist, since 2 patients dying of other causes showed it at autopsy.

Most of the plasma after quick freezing is stored in thermostatically controlled refrigerators at -10°F , protected by electric thermometers and an alarm

blood is set aside ready for use. In an emergency, if an Rh typing has not been done on the patient, an attempt is made to give an Rh— blood or plasma, but we deplore unnecessary emergencies, preferring to set up bloods unnecessarily a day ahead rather than to try to do important laboratory work in a hurry at the expense of routine work. In case a blood is not called for at the time specified, the ward is called, and if the patient does not need it, it can be used for someone else, since it has not left the refrigerator.

There are two means of preventing blood from being given to the wrong patient. The first is to

FIGURE 5 The Sterile Filtering Set.

On the right is the fine-mesh stainless-steel sieve, on the left, the stainless-steel funnel.

system. Some plasma is kept at room temperature and some, diluted with saline solution, is stored in the refrigerator. Both are ready for immediate use after negative cultures, and are useful for emergencies. We have distributed plasma to other hospitals for storage, and are equipped to give out to any hospital plasma in Fenwal flasks, with sterile glass vent tubes and rubber tubing ready for connecting to intravenous apparatus.

ADMINISTRATION OF BLOOD AND PLASMA

In requisitioning blood or plasma the physician fills out a requisition with the patient's name, number, ward, diagnosis, reason for wanting blood or plasma and the time it is wanted — usually twenty-four hours in advance — except in emergencies. This form, accompanied by 5 cc. of the patient's blood, arrives in the bank; the patient is then grouped by two persons and the oldest blood of that group on hand — on the average three days old — is selected, two cross-matchings are done, and the

have the person who is to make the transfusion come and get it, checking its tag, which has already been marked with the patient's name; the second is to let such a person take only the blood for one patient at a time. The medical services have a wise additional safeguard in the form of still another cross-matching done by the intern at the patient's bedside.

Just before the blood is given out, it is filtered through a stainless steel sieve, 14 cm. in diameter with a 0.2-mm. mesh in its bottom. It rests in a stainless steel funnel set in a flask. The whole has been autoclaved and the sieve moistened with saline solution to break the surface tension. This eliminates both large and irregular filters such as gauze or beads, or the Baxter and Cutter filter drips, which are excellent for filtering but altogether too frequently cause a reduction or stoppage of blood flow. If the blood is used immediately, the chance of the formation of a fresh plasma or blood clot is negligible. Forty-eight of these sets are kept on hand, a number well in excess of any day's transfusions.

When the blood arrives at the patient's bedside, the person administering it is supposed to check its tag with the patient's name, particularly if a nurse brought the blood from the bank. There has been some difficulty due to bloods' being improperly handled — that is, either they have been heated by some misinformed person, or after being exposed to room air in the filtering process they have been put in a ward refrigerator for a few days. Since these practices promote bacterial growth and hemolysis, we have attempted by education to eliminate them.

The fluids are administered on the private and semiprivate wards by two nurses specially trained in

always to feel for the radial pulse after application of a tourniquet. The antecubital veins are avoided in case the patient should have a protracted illness. We do not hesitate to use and have found to be satisfactory the sternal route of fluid administration. All persons, interns and nurses, are instructed in these measures and are told to sit with all patients having transfusions for the first five minutes of running, because within that time the warning of a fatal reaction usually appears. At the end of the transfusion the card attached to the bottle neck is filled out as to reaction, blood flow and so forth and returned to the bank. One per cent to 2 per cent of these cards are not returned, but by pressure being kept on the head ward nurses they are usually sent in.

In case of a reaction, the transfusion is stopped, the blood is returned to the bank for regrouping, and the patient is put on an alkalinizing regime. The urine and blood are subsequently examined for free hemoglobin.

Plasma is requisitioned similarly to whole blood, but its administration is different. It is melted in a rapidly circulating water bath at body temperature regulated by hand and checked by a thermometer. There are, however, special metal racks for the purpose of melting thirty-two units at a time in case of disaster. Plasma is administered through an intravenous set with a Baxter or fine-mesh Cutter filter inserted in the place of the usual drip bulb. Below the filter lies a three-way stopcock to permit the use of a syringe for rapid administration. This system works well; there is little clot and no stoppage of flow due to it. Furthermore, it is certain that there will be no trouble from minute pulmonary infarcts. Shortly after the inauguration of the bank, we began to use these filters on the commercial dried plasma then being administered in the hospital and cut the reactions down from a fair degree of frequency to a rare one. There are one hundred sterile filter sets on hand at all times in case of civilian disaster, such as a fire or a bombing.

There is a charge of \$25 for the plasma, the same as for blood, but we are far more liberal in giving it out to patients who can neither replace it nor repay us. This is done because plasma is considered in large measure a byproduct. In case of disaster its administration is given free.

Records and Reactions

The tags on the plasma and whole-blood flasks give the final record of what happened to the blood and are filed with the donors' cards. From time to time there are brought up to date the number of rejected donors and the reasons for rejection, the number of bloods used for plasma, the whole bloods given and the reactions. An attempt is made to find the reason for the reaction in each case, particularly in serious ones; for this purpose the facilities of the Blood Grouping Laboratory are available. To date, the percentage of reactions since the installation of

FIGURE 6. *The Administration of Whole Blood After Filtering. Note the flask of saline on the table with which the infusion was started by the intern.*

intravenous work and on the general wards by interns. This use of nurses, started as a war measure, has proved to be highly satisfactory. They can be taught a single dependable method of therapy, after learning which there is no shift to new ideas and no deviation from accepted standards of safety. Interns have been retained as fluid administrators on the wards because of the value of their learning the fundamentals of needle insertion and intravenous therapy. The nurses sharpen their own needles. They are taught to begin all intravenous administration with a saline or glucose solution and after the fluid is running well, to shift to blood or plasma. This saves both material and veins. They use, except in emergencies, the most peripheral veins first (usually those on the hand) with careful splinting of the part and good sterile technic. They are taught

the metal sieves has remained constant at 6.3 per cent. This includes 1.2 per cent of serious reactions as evidenced by high fever and chill, 1.5 per cent of minor chill and temperature reactions probably due to foreign matter in needles, bottles or tubing, 2.6 per cent explicable on an anaphylactic basis, and 1 per cent of a vague class of complaints, many of which are coincidental with, rather than caused by, transfusion. These figures are based on the first four thousand transfusions after a preliminary survey. There was 1 patient with serious post-transfusional oliguria who died on the operating table. This was thought to be a case of an anti-Rh hemolytic reaction. The death occurred prior to the present system of Rh determinations.

CONCLUSION

The methods and rules used by the blood bank of the Massachusetts General Hospital have been derived partly from the experiences of others and partly from our own experiences. They form a workable system that may, and we hope will, help other hospitals to set up blood banks or to iron out the many difficulties into which such institutions run.

DIET IN PREGNANCY

CHARLES LEAVITT SULLIVAN, M.D.*

BROOKLINE, MASSACHUSETTS

WARTIME rationing of foods and the difficulties encountered in purchasing a selection of unrated foodstuffs present a serious problem from the nutritional standpoint to the pregnant woman and her developing fetus. Various surveys^{1, 2} in the past have shown relative dietary deficiencies directly paralleling economic status, but the present emergency places all women in the same category. The relation between the pregnant woman and the fetus is one of aggressive parasitism on the part of the latter, all its requirements being taken from the maternal organism. Eugenically the parturient state calls for the very best, from a nutritional standpoint, that the civilized state can present, so that the growing fetus will have available the maximum and optimum material essential to assure generations free from anomalous deficiencies of growth, as in the teeth, female pelvis and so forth, without extracting too great a toll from the parent host. It is the responsibility of the physician conducting prenatal care to make every effort to ensure the physical stamina and constitutional adequacy of the newborn infant.

The well-defined clinical syndromes of specific dietary deficiencies are too well known to require elaboration and are not common in obstetrics, although occasionally reported in the literature.³ The vast majority of deficient nutritional states, however, do not reach levels productive of a clinical syndrome, but rather present a myriad of bizarre complaints that too often are dismissed by the attending physician with a mild sedative or explained away on a psychoneurotic basis. Thus, in 84 per cent of cases Williams and Fralin⁴ found that such common complaints as nausea and vomiting of early pregnancy and easy fatigability, numbness and

muscle spasm in late pregnancy were associated with below-standard consumption of vitamin B.

It is generally agreed that the average pregnant woman engaged in domestic affairs requires approximately 2500 calories a day to carry on her increased metabolic activities.^{4, 5} This figure varies between 2000 and 3000 calories for the average woman of one hundred and twenty to one hundred and fifty pounds, depending on the state of her nutrition at the onset of pregnancy. Thus, although in the vast majority of cases it is prudent to restrict weight gain during pregnancy to 20 to 25 pounds, some women prior to conception are below average minimal standards for height and weight, and in them the parturient state with its general enhancement of metabolic activity and relief of psychoneurotic tension brings about an opportunity to correct long-standing imbalance between height and weight. The reverse is of course true in obese women, and their diets should be accordingly restricted from a caloric standpoint. Studies by Waters⁶ indicate that a weight gain of over 22 pounds is retained post partum in 60 to 80 per cent of cases, except in hydropic patients. It is of course important to distinguish carefully between hydropic and stereoplastic weight gain, both from the dietary viewpoint and from that of active prophylaxis against impending toxemia. The growth of the fetus is parasitic,⁷ and most obstetricians believe that the weight of the fetus cannot be controlled by that of the mother unless the latter be placed on starvation rations. Adair⁷ and others found the growth of the fetus to be independent of the intake of fats and carbohydrates if the total calories were adequate. Intrauterine deficiencies affecting the fetus—for example, rickets—may be produced by starvation and depletion of maternal mineral reserves, as pointed out by Maxwell, Hu and Turnbull,⁸ Rector⁹ and

*Assistant visiting obstetrician and visiting obstetrician to outpatients, Department of Obstetrics, St. Elizabeth's Hospital, Boston

others. Sontag¹⁰ believes that scurvy tends to appear early and in a malignant form in children whose mothers suffer from vitamin deficiencies.

Attempts have been made to correlate deficient diets with the major and minor complaints of pregnancy, with results that are not conclusive at this time. Ebbs et al.¹¹ found a high incidence of miscarriage, stillbirths, prematurity and minor complications in pregnant women on deficient diets, but Williams and Fralin¹ were unable to find a direct correlation, admitting, however, that such defects might not be present until a later date when the full histories of the child and mother were available.

The essential elements in an obstetric diet are protein, fats, carbohydrates, calcium, phosphorus, iron, iodine and the vitamins. With adequate amounts of these elements all the requirements will be adequately met. Furthermore, the use of sodium chloride should be restricted.

Protein. Protein, both animal and vegetable, in quantities of 80 to 100 gm. daily, is at long last recognized as an essential for the obstetric patient. In the past, fear of kidney complications or the presence of kidney disease has caused a restriction in protein consumption, with a resultant deficiency syndrome of anemia, loss of muscle tone, edema and lowered resistance. In late pregnancy the maternal organism stores over 100 gm. of protein daily in anticipation of labor and lactation.

Fats. These are also required in quantities of 80 to 100 gm. daily and are utilized primarily for energy and for enhancing the utilization of vitamins.

Carbohydrate. This is the basic food element that allows the greatest latitude in varying consumption to control adequate caloric intake. It is estimated that 100 to 300 gm. daily is necessary to provide energy for the mother and easily assimilable food for the fetus. Whereas protein consumption may be placed at a minimal level to assure the essential elements, carbohydrate intake may be varied to suit the caloric requirement in relation to excessive weight gain. Carbohydrates are the most easily obtained food-stuffs in rationed and wartime diets, and therefore may easily assume too great a percentage of the total caloric intake. This is important, as pointed out by Becker et al.,¹² since increased amounts of thiamine chloride are necessary when the carbohydrate content of the diet is raised.

Calcium and phosphorus. Calcium intake in pregnancy should attain levels of 1.5 to 2.0 gm. daily. The calcium-phosphorus ratio and metabolism are extremely important, and failure to maintain them at desired levels leads to complaints of cramps, insomnia and headaches. Deposition of calcium in the fetal bones begins at the fourth month and continues to term, with increased demands from the seventh month on, so that at term the fetus contains approximately 24 gm. of calcium.¹³ Dental authorities do not believe that this demand on the mother is productive of tooth decay, as was formerly thought, but

it is recognized that marked calcium deficiency may lead to postpartum hemorrhage due to uterine atony. Hart and Noble¹⁴ advocate the intravenous use of calcium in such situations.

Iron. The daily requirement of iron varies between 20 and 30 mg., depending on the state of the blood at the time of conception. It has been shown by Hunscher¹⁵ that hemoglobin levels parallel adequacy of iron in the diet. The relative amount present in the maternal organism varies with changing fluid levels, but it is known that at term the placenta and fetus contain approximately 900 mg. of iron, so that the absolute demand is constant.

Iodine. In this part of the country one need not be concerned with the intake of iodine as in endemic goiter belts, but the intake may be assured by the use of iodized table salt in selected cases.

Vitamins. The daily requirements of the vitamins are difficult to determine because of the multiplicity of their effects on the human organism. They are estimated on the basis of the smallest amount that will prevent visible and recognizable symptoms of deficiency, with an added safety factor to cover individual variations. Vitamin A is important to promote growth and fertility and for the maintenance of epithelial tissue. Its effect on visual purple is well known. It is estimated that 6000 to 9000 international units is required daily. Chief among the requirements of the vitamin B complex is that of thiamine chloride, and its adequate intake will ensure the intake of sufficient amounts of the remainder of the complex. Insufficiency of thiamine chloride is known to cause undue fatigue, loss of appetite and other gastrointestinal upsets, headaches and mild neuritis. The importance of this vitamin concerns every cell in the body rather than any one organ or system. The daily requirement varies between 1.0 and 1.8 mg. of thiamine chloride. Vitamin C requirements are met by an intake of 1500 international units or 50 to 100 mg. of ascorbic acid daily. Vitamin C is concerned with the cementing of intracellular material, and deficiencies are manifest in clinical and subclinical scurvy, the teeth, lack of resistance to infection and predisposition to brain hemorrhage in the fetus. Ley¹⁸ states that vitamin C stimulates the production of corpus luteum hormone. Vitamin D regulates the utilization of calcium and phosphorus. The daily requirement varies between 600 or 1000 international units.

Sodium. The sodium balance in pregnancy is usually positive and more than adequate for fetal needs. Restriction of sodium chloride is advisable there should at least be limitation of its use to cooking with absolute prohibition of its use at table. This is advisable both because of its relation to fluid retention and toxemia and because, as pointed out by Wadlow and Pomerance and Daichman,¹⁷ depletion of maternal salt leads to a shorter and easier labor, probably owing to dehydration of the cervix and uterus leading to more efficient and effective contraction

With an understanding of the requirements of the maternal organism and the demands made on it by the growing fetus, one can appreciate the fact that the one variable concerned is the total caloric intake. Rationing and the difficulty of securing foodstuffs are not important from this standpoint because of the ease in securing carbohydrate. Adequate supplies of the essentials are, however, at times difficult to secure, and it behooves the physician to instruct his patients concerning them, and to advise them to make every effort to obtain the essential nutrients by wise use of their rationing points. Every woman should be advised to include the following in her daily diet:

One quart of whole milk.

Two medium-sized oranges, three or four medium-sized apricots, four or five medium-sized stewed prunes or 8 ounces of tomato juice.

One egg.

Two to three servings of whole-grain or enriched bread or of cereal.

Two tablespoonfuls of butter or fortified margarine.

One serving of meat, fish, poultry or cheese, with liver or other organ meat once a week.

One or more cupfuls of fresh vegetables, including one green or yellow vegetable in addition to potato.

It is an accepted fact that foods vary in their nutritive values with storage, handling, cooking and preserving. From the standpoint of nutrition, liver is the richest of all meats in combined nutritive values. One serving of it contains more vitamin A and riboflavin than does a serving of any other natural food. It is an excellent source of iron, protein and thiamine, and even when cooked provides a fair amount of vitamin C. Vitamin B is water soluble and is readily destroyed by heat and by the addition of alkali to the cooking water. Since green vegetables and potatoes are good sources of thiamine before cooking, correct cooking practices should be used to preserve the vitamin in the cooked product. Since thiamine cannot be stored in the body, it is daily necessary to eat foods containing adequate amounts of it. Refinement is the enemy of thiamine, which is found in all living tissue; whole-wheat cereals, beans, pork, beef, liver and chicken are perhaps the richest sources. If care is taken to use whole-grain products, enriched and restored cereals, beans, peas and meats and to see that food is not overcooked, a deficiency of thiamine will not occur. Vitamin C is readily destroyed by heat; thus it is best taken in the form of raw vegetables and fruits. This vitamin, like vitamin B, is not stored in the body, is water soluble, and is readily destroyed by an alkali medium. Owing to the presence of 7-dehydrocholesterol, a fatlike substance,¹⁹ in the body and to the

effect of the ultraviolet rays of the sun, the aforementioned chemical substance is changed to vitamin D. Vitamin D is one of the vitamins that can be stored in the body, and when daily exposure to the sun and dietary intake causes the formation of more than is needed, the excess is naturally stored. With the presence of ultraviolet rays, either natural or artificial, the manufacturing and storage process is continuous. Thus, daily periods of sunning will help to attain adequate amounts of this vitamin, but the pregnant woman should supplement her vitamin D intake with one of the fish-liver oils. This may be taken in concentrated form with dicalcium phosphate, thus ensuring adequacy of the calcium intake as well as of that of vitamin D. Iron should be included in the diet in proprietary form as indicated, the actual amounts being determined by blood studies at the time of the first visit and during the last trimester.

SUMMARY

The daily dietary requirements of the average pregnant woman are reviewed, and a basic list is presented of food elements that with minimal supplemental additions will provide for an adequate normal nutritive relation between the pregnant woman and the fetus.

CLINICAL NOTE

RUPTURE OF A LEFT TEMPOROSPHENOIDAL BRAIN ABSCESS INTO THE VENTRICLE

REPORT OF A CASE, WITH RECOVERY

LOUIS E. WOLFSON, M.D.

BOSTON

RUPTURE of a temporosphenoidal abscess of the brain into the lateral ventricle is an event that has rightly been considered fatal. The recording of such an occurrence by roentgenograms during life, together with complete recovery following the use of one of the sulfonamide drugs, warrants the report of the present case, especially since no similar case report has been found in the literature. With increasing use of the sulfonamide drugs it is reasonable to expect recoveries in similar cases.

REPORT OF CASE

M. K., a 56-year-old, totally blind piano tuner, was first seen on January 8, 1943. He had been blind and had had a chronic mastoiditis on the left ever since the age of 5, following an attack of scarlet fever. Ten days before consultation he developed an upper acute respiratory infection that was followed by an exacerbation of the mastoiditis. Two days before, a left-facial paralysis developed. The patient had been given 4 gm. of sulfadiazine daily for the last 3 days.

Examination showed a pulsating discharge of the left middle ear with complete left-facial paralysis. The nose, throat and right ear drum were essentially normal. There was no tenderness in the mastoid areas. The neck was somewhat rigid, and a definitely positive Kernig test was obtained. There was no sensory aphasia.

The patient was referred to the Beth Israel Hospital, where x-ray films showed a sclerosed left mastoid process with no evidence of bone destruction. A lumbar puncture showed clear fluid, with a pressure of 250 mm. of water; a cell count showed 42 fresh and 3 crenated red cells and 89 white cells, with 26 polymorphonuclear leukocytes, and 63 lymphocytes. The usual postauricular radical mastoid operation was performed on January 11. A thick cortex was found, and the antrum contained foul granulating tissue under apparent pressure. Some cells along the facial canal were broken down and filled with granulating tissue and pus. There was a small area of erosion in the area of the tegmen antri 1 cm. in diameter, which was removed. The dura in this area appeared normal except for slight thickening. Cultures of material from the mastoid area showed *Staphylococcus albus* and a nonhemolytic streptococcus. The postoperative course was normal, and there was motion of the left angle of the mouth 2 days later. Sulfadiazine was given in a dosage of 6 gm. daily, the blood level being maintained at about 7 mg. per 100 cc.

On January 15, 5 days postoperatively, there was a slight rise in the temperature and the patient appeared to be somewhat drowsy. There was a definite loss of motion in the right arm and leg. The patient was sent to the operating room and a lumbar puncture was done. This showed a pressure of 250 mm. of water; the white-cell count of the fluid was 110, with 30 polymorphonuclear leukocytes and 80 lymphocytes, and the red-cell count 74. The mastoid was reopened, and the area of the tegmen antri was widely exposed, leaving an area 2.5 cm. in diameter exposing the dura in this area. The dura felt tense, and granulating tissue was present. It was incised, the brain was incised, and a cannula was inserted for a distance of 3 cm., when foul-smelling, thick, creamy pus was obtained. A semirigid rubber catheter was inserted until it seemed that the bottom of the abscess was reached. The outer part of the catheter was split and sutured

to the scalp in this area. Cultures of the pus showed *Staph aureus*, diphtheroids and a nonhemolytic streptococcus. Half an hour after the patient was brought back to his room, the stupor had disappeared and most of the paralysis of the right arm and leg had cleared. Recovery was uneventful except

FIGURE 1. Roentgenogram Showing Lipiodol in the Sinus Tract and Left Ventricle.

for a sharp rise in temperature on January 28, at which time the temperature rose to 104°F. The dressings and catheter were changed and the sulfadiazine level, which had been maintained between 9 and 10 mg. per 100 cc., was increased by the use of sodium sulfadiazine intravenously. On the following day the sulfadiazine level was 13.9 mg. The ten

perature returned to normal, and the postoperative course was uneventful except for the discharge, which had become watery with a small amount of visible pus.

One week later, it was decided to ascertain the size of the cavity. At the suggestion of the roentgenologist, lipiodol (about 5 cc.) was inserted in the cavity through the catheter until there was an overflow. X-ray films were taken immediately, the report being as follows:

A sinus tract was visualized extending first in the direction of the tube. It was 0.5 cm. in width and irregular in contour. The oil had entered the inferior horn of the left ventricle from its lowermost medial aspect and it was first seen filling this lower horn (Fig. 1). After some time it

shifted throughout the ventricular system and there was only a faint coating in the left lower horn. Stereo x-rays taken in the anteroposterior and left lateral positions revealed additional facts as follows. In the face-down position, a larger amount of the oil occupied the left anterior horn. A group of droplets was seen in the right anterior horn (Fig 2). The left posterior horn was filled with

same distribution of oil (Fig. 3). There was air filling of the dilated right lower horn.

Recovery was uneventful. Further x ray films showed lipiodol at the base of the spinal column. The catheter was gradually shortened and the sulfadiazine gradually diminished. The catheter was finally removed, and the patient was discharged on February 8. X-ray films taken on March 19 showed small droplets of lipiodol in both the lower and posterior horns and along the basal cisternae. There was no evidence of intracranial air.

In May the patient returned to his work and has continued well to the present writing.

COMMENT

Abscess of the brain secondary to a chronic mastoiditis is always a grave event. Many cases go undiagnosed and terminate fatally before appropriate therapy can be given. In the present case, although the diagnosis was evident and surgery had been performed, development of sudden hemiplegia led to the diagnosis of the extension of the abscess into the brain tissue. The abscess was drained, following which lipiodol injected into the cavity showed connection of the abscess with the ventricle. It appears that the use of a high concentration of sulfadiazine probably checked further spread of the infection.

Rupture of such an abscess into the ventricle is extremely rare, and is generally seen only at autopsy. X-ray studies of such an event in life have not heretofore been made.

air, and there were several small lipiodol droplets and small air-filled spaces that could not be identified. The lateral view taken in the left position showed about the

MEDICAL PROGRESS

BLOOD BANKS AND BLOOD TRANSFUSION*

JOSEPH T. ROSS, M.D.†

BOSTON

BLOOD transfusion and the use of various blood derivatives are among the most useful and commonest forms of therapy. The recent great increase in the use of transfusion therapy has been due largely to the increasing recognition of the benefits to be derived from administration of blood or plasma in a wide variety of diseases, to the practical development of blood banks, which have made the administration of blood and plasma extremely simple and economical, and to the need of the military services for plasma and blood. Each of the numerous preparations of blood and plasma now available — unmodified blood, fresh citrated blood, blood stored in various mixtures of citrate and glucose, suspensions of erythrocytes, refrigerated plasma, frozen plasma, desiccated plasma and various preparations of purified

albumin and globulin — has certain advantages and certain limitations that make it especially useful in some conditions but unsatisfactory in others. Transfusion of blood or plasma is often of value in the following diseases: anemia; hemorrhagic diseases; hemorrhage, shock and burns; hypoproteinemia and infections. The preparations most satisfactory in the treatment of each of these conditions will be discussed, as well as the necessary precautions and the commoner transfusion reactions.

Several excellent books dealing with blood transfusion and blood banks have appeared during the last few years. Kilduff and DeBakey¹ have thoroughly reviewed the entire literature of transfusion and present excellent practical information on the establishment and operation of a blood bank. Wiener² has again revised his classic monograph, *Blood Groups and Transfusion*, and has added valuable chapters on the Rh factor and on the use of stored blood. Mudd and Thalhimer³ have edited a collection of papers on the theoretical and practical

aspects of blood and blood-substitute therapy that summarizes most of the important American contributions on these topics. Riddell⁴ discusses the practical details of transfusion therapy.

ANEMIA

The use of transfusion in the treatment of anemia is directed toward increasing the oxygen-carrying capacity of the blood and is achieved by supplying physiologically functional erythrocytes to the recipient. In certain cases of acute hemolytic anemia, in patients who have sustained a large and rapid loss of blood from hemorrhage, and in some acute types of bone-marrow depression transfusion is often a life-saving, emergency procedure. In certain chronic hemolytic anemias, and in patients with chronic bone-marrow depression (aplastic anemia, myelophthisic anemia, uremia and hepatic disease), transfusions may sustain life for months and occasionally years. Fortunately, the anemias most frequently encountered — iron-deficiency anemia and pernicious anemia — usually respond rapidly to iron or liver-extract therapy, and transfusion in such cases is rarely necessary, even when the red-cell count falls to levels as low as 1,000,000.⁵ Preoperative and postoperative transfusions are of considerable value in anemic patients who must undergo immediate surgery and in those in whom considerable blood loss may occur. Such transfusions aid in the prevention of shock and shorten the convalescent period.

To be successful, the transfusion treatment of anemia must provide the recipient with functional erythrocytes that will survive during the acute phase of the disease. There is little doubt that erythrocytes transfused immediately after withdrawal from a donor fulfill this requirement. Several investigators⁶⁻⁸ have demonstrated the survival of transfused erythrocytes for periods of one hundred and twenty to one hundred and thirty days, and the clinical efficacy of transfusions of fresh blood is practical proof that such cells survive during the critical periods of anemia.

Considerable controversy has arisen concerning the relative merits of unmodified blood and citrated blood for transfusion purposes.^{9, 10} Although the administration of unmodified blood is more physiologic than that of citrated blood and in skillful hands apparently produces slightly fewer reactions, it requires an exacting technic and always carries the danger of introducing blood clots or air emboli into the veins of the recipient. From a practical standpoint, the use of citrated blood is much more convenient, safer and just as satisfactory therapeutically.¹¹ Sodium citrate is relatively nontoxic, since 6 to 8 gm. may be injected intravenously during a ten-minute period without producing symptoms,¹² and larger quantities may be given over longer periods of time without ill effect. It is rapidly oxidized and excreted, 90 per cent being removed from

the blood within ten minutes.¹³ Transfusions of even large amounts of citrated blood are not likely to produce symptoms of citrate toxicity, since the citrate contained in 2500 cc. of citrated blood (6.2 gm.) is less than the toxic dose, and furthermore, considerable amount of the citrate is metabolized during the time required to administer this volume of blood.

Sodium citrate exerts little or no effect on the post-transfusion survival of erythrocytes provided citrated blood is administered to the recipient within a few hours of the time it is withdrawn from the donor.^{6-8, 14} Longer storage, however, exerts an extremely deleterious effect on erythrocytes, the post-transfusion survival of such cells varying inversely with the length of time that the blood is stored.^{7, 8, 14, 15} Eighty per cent of the erythrocytes of citrated blood stored for seven days or longer are destroyed within twenty-four hours after transfusion,^{8, 14} and consequently such blood is quite unsatisfactory for use in the treatment of anemia. Furthermore, transfusions of blood stored for too long a time may actually be dangerous because of hemolysis of the transfused cells is sometimes so rapid that hemoglobinemia and hemoglobinuria occur.^{16, 17}

Rous and Turner¹⁸ observed that the addition of glucose to citrated blood decreased its tendency to undergo spontaneous hemolysis and presumably prolonged the survival of stored cells in vivo after transfusion. The large volume (1666 cc.) of this mixture and the amount of sodium citrate (12.6 gm.) required for the preservation of 500 cc. of blood make impractical the use of this preservative, though it preserves erythrocytes fairly well.^{15, 19} During the last ten years, under the stimulus of the war and the rapidly developing civilian blood-bank services, an intensive search for better erythrocyte preservatives has been carried on in most civilized countries. The greatest stumbling block encountered in these studies has been the difficulty of assessing the value of any given preservative. Numerous in vivo studies of blood preservatives have been made, but these appear to have little positive value in indicating the probable behavior of erythrocytes after transfusion. It has now been established fairly definitely that the prevention of in vitro hemolysis, the preservation of relatively normal fragility in hypotonic saline solutions, various lytic agents, trauma, the maintenance of relatively normal potassium and phosphate concentrations within the cells and a normal pH have little significance in indicating the length of survival of stored cells after they are transfused.^{7, 16, 20, 28} Unfortunately, no investigators of cell preservatives have employed one or more of these criteria in evaluating the efficacy of their preparations, and have failed to refer to the only test that is of actual significance, that is, the survival in vivo of the stored erythrocytes after transfusion.

Attempts to determine on a quantitative basis the actual length of survival of transfused cells have been made with differential agglutinating techniques^{8-9, 15, 29} and with the use of radioactively labeled erythrocytes.^{14, 17, 30} Although both methods are subject to criticism, it is apparent from such studies that cells can be stored in glucose-citrate mixtures for at least two weeks, with an expected survival of 80 to 90 per cent of the transfused cells for at least forty-eight hours after transfusion. A glucose-citrate mixture buffered with sodium phosphate to a pH of 7.4 has been recommended by Denstedt and his associates²⁹ and appears to be one of the most satisfactory preservatives studied.

Although this preservative is satisfactory for use in civilian blood banks, it has not as yet been developed sufficiently to allow shipment of whole blood to the battlefronts. Consequently, to supply the military services with a blood substitute plasma must still be separated from blood and the erythrocytes discarded. Attempts are being made to salvage these discarded erythrocytes and to make them available for transfusion purposes. They have been resuspended in various saline and glucose solutions and administered to patients in the same way that whole-blood transfusions are given.^{31, 32} Therapeutic response to such erythrocyte suspensions has apparently been about the same as would have been achieved from administering erythrocytes preserved in citrated blood for the same length of time. Such suspensions do not prolong the allowable preservation period of erythrocytes, but they do allow the use of waste red cells from plasma-processing centers. Erythrocytes stored in blood banks are as a rule unsatisfactory for transfusion purposes by the time the plasma is separated from them, and resuspension of such old cells in the fluids so far studied cannot be expected to restore their potentiality of post-transfusion survival.

The interesting possibility exists that the breakdown products of transfused erythrocytes accelerate the production of new red cells by the bone marrow. Cruz, Hahn and Bale³³ observed that radioactive iron liberated from erythrocytes by acetylphenylhydrazine hemolysis was rapidly reutilized for the synthesis of new hemoglobin. Ross and Chapin¹⁴ found that although transfused red cells might be rapidly destroyed, the hemoglobin iron of these cells quickly reappeared in newly formed erythrocytes, and the rate of reutilization of this hemoglobin iron was much more rapid than it would have been if iron alone had been given by injection. These observations suggest that even though donor erythrocytes are broken down a few days after transfusion, they may furnish easily utilizable building stones for the formation of new red cells.

Solutions of hemoglobin have been advocated as a substitute for blood,³⁴ and Amberson and his associates^{35, 36} have been able to maintain life in cats with such solutions. The hazards associated with the

administration of the required amounts are too great to justify their clinical use, and in spite of their capacity to combine with and liberate oxygen³⁷ it is unlikely that they can ever be expected to replace or even supplement the physiologic activity of erythrocytes.

In summary, if it is desired to supply functional erythrocytes to a recipient, fresh citrated blood is probably the most desirable preparation to use, but citrated blood stored not longer than two days can be used, and blood stored in glucose-citrate mixtures for one or two weeks may also be satisfactory.

HEMORRHAGIC DISEASES

Transfusion is the only effective treatment for several types of hemorrhagic disease, and is still of considerable value in the control of several other types for which more specific therapeutic measures are now available. It is used in these diseases to supply some substance that is essential for the proper functioning of the clotting or hemostatic mechanisms but that is decreased in amount or absent in the diseased patient. The classic theory of blood coagulation is still of considerable aid in considering the hemorrhagic diseases from a therapeutic viewpoint, although it is undoubtedly oversimplified and should not be accepted too literally.

Interference with any one of these factors delays or prevents the clotting of blood, but from the practical clinical standpoint disturbances of only two of these factors — prothrombin and thromboplastin — are encountered.

Prothrombin deficiency is now known to be the cause of hemorrhagic disease of the newborn, and of the hemorrhagic states encountered in cases of biliary obstruction and of severe liver damage and in diseases of faulty absorption of fat and the fat-soluble vitamins — for example, sprue and ulcerative colitis. The anticoagulant drug dicoumarin produces its effect by depressing the formation of prothrombin. Parenteral administration of vitamin K controls many of these conditions, but it does not elevate the plasma prothrombin or control a hemorrhagic tendency if liver damage is severe.³⁸ Furthermore, the latent period before the effect of vitamin K can become manifest and decrease the bleeding tendency is occasionally too long, even in patients with normal hepatic function. In such cases transfusion of blood or plasma is the only effective means of increasing plasma prothrombin, and if administered in adequate amounts these substances will control even the severest cases of prothrombin deficiency.³⁹

It is important to remember, however, that prothrombin is a labile substance and is rapidly destroyed in alkaline solutions⁴⁰ and in blood or plasma kept at room temperatures. Prothrombin activity is lost more slowly at 4°C.,⁴¹⁻⁴³ and plasma separated from freshly drawn blood and frozen immediately maintains most of its prothrombin activity for several months.⁴⁴ Prothrombin is also preserved in desiccated blood plasma, but is destroyed during reconstitution if the reaction of the solution is not maintained near neutrality.⁴⁰ Reconstitution of desiccated blood plasma with a 0.1 per cent solution of citric acid instead of with distilled water keeps the reaction of the plasma near neutrality and maintains a satisfactory prothrombin content.

The greatly prolonged clotting time encountered in hemophilia is now known to be due to a deficiency of thromboplastin. It was formerly believed that this deficiency was due to abnormal resistance of the blood platelets, which were supposed not to break down and liberate thromboplastin in the normal fashion.⁴⁵ It now appears that a more important deficit exists in the plasma itself. Patek and Stetson⁴⁶ and Lozner, Kark and Taylor⁴⁷ demonstrated the efficacy of platelet-free normal human plasma in reducing the coagulation time of hemophilic blood, both in vitro and in vivo, and showed that plasma from hemophilic subjects contains decreased amounts of this active thromboplastin-like substance. Subsequent investigations by Taylor and his associates,⁴⁸⁻⁵⁰ have shown that normal plasma contains a so-called "globulin substance" effective in accelerating blood coagulation in cases of hemophilia. This substance is apparently quite stable and is well preserved in blood or plasma kept at 4°C. and in frozen and desiccated plasma. Injections of any of these preparations usually serve to prevent or control the hemorrhages of hemophilic patients. Purified preparations of globulin substance⁵¹ and of rabbit thrombin⁵² have also been prepared that have been efficacious as local hemostatic agents in normal as well as in hemophilic subjects.

Except for splenectomy, transfusion of fresh blood is the only procedure of specific therapeutic value in patients with thrombocytopenic purpura, and occasionally even fresh blood fails to reduce the bleeding time or to allay hemorrhage in this disease. The characteristic marked reduction of platelets does not interfere with the clotting mechanism itself, but is responsible for the failure of the clot to retract, and perhaps for the prolonged bleeding time. The exact relation between the capillary abnormality existent in this disease⁵³ and the decrease in blood platelets is obscure, but as a rule transfusion of fresh blood does increase the platelets of the recipient and decrease the bleeding time.⁵⁴ There is little difference in this respect between the efficacy of unmodified blood and that of fresh citrated blood, but injections of stored bank blood or plasma have been shown to

have little effect in controlling the hemorrhagic tendency, probably because of the rapid degeneration of the blood platelets in stored blood.⁵⁵

HEMORRHAGE

The plasma and erythrocytes lost during active hemorrhage are best replaced by transfusions of blood, although plasma may be used if the loss of red cells has not been excessive. In cases of extreme blood loss in which the hemoglobin concentration has fallen to extremely low levels blood should be used, since administration of plasma will further dilute the remaining cells and precipitate or aggravate tissue anoxia.⁵⁶ In treating patients with hemorrhage it is essential to combat or prevent reduction in the effective blood volume before active shock occurs, and transfusion must never be delayed until the blood pressure begins to fall or signs of tissue anoxia appear, since it is far easier to prevent the onset of shock than it is to treat it once it has developed.⁵⁷

The belief that transfusion of blood in cases of gastrointestinal bleeding may raise the blood pressure and actually "blow off" the clot from the bleeding site is erroneous. The rapid infusion of 500 cc of blood within five or ten minutes produces an elevation of blood pressure of only 10 mm. of mercury and Kordenat⁵⁹ demonstrated experimentally that such increase of pressure is inadequate to dislodge recently formed thrombi from small arteries. Clinical experience has also proved that the transfusion of blood in cases of bleeding duodenal ulcer is frequently a life-saving measure and does not precipitate a recurrence of hemorrhage.⁵⁰

The transfusion of unmodified blood in the treatment of hemorrhage has been advocated in the belief that it is more effective than citrated blood in promoting coagulation and hemostasis. The greater availability of citrated blood in blood banks and the rapidity and ease with which such blood can be procured and administered in cases of emergency appear to outweigh the slight advantages claimed for unmodified blood.⁵⁸ Theoretically, fresh blood may be more effective than stored blood because of the degeneration of platelets and prothrombin in the latter, but practically, stored blood is quite satisfactory.

Bleeding into the pleural or peritoneal cavity may be so excessive that shock is produced. Active transfusion — the transfusion of this blood into the patient's veins — has been suggested as an emergency procedure.⁶¹ The mortality from such transfusions has been between 2 and 4 per cent,⁶¹⁻⁶³ due usually being attributable directly to infusion of contaminated blood or of blood that has remained in the peritoneal cavity for seventy-two hours or longer. Because of the danger of the procedure it should be employed only in cases of extreme emergency when other blood or plasma cannot be obtained.

(To be concluded)

CASE 30061

PRESENTATION OF CASE

A twenty-three-year-old woman was admitted because of swelling in the lower back of three months' duration.

The patient had been in excellent health until about eight months before entry, when she developed pain in the lower midback. This was severe only when she tried to bend, and it did not radiate. It lasted for about five months, improving slowly but steadily. Three months before admission she noted the gradual onset of swelling in the lower midback. The swelling increased in size, but there was no pain. She had no weakness in the back or legs or any other symptoms.

One sister had arrested tuberculosis.

Physical examination showed a well-developed, well-nourished girl in no distress. The heart was normal. Slight "wheezes" were heard in the right lung. The abdomen was normal. A cystic, fluctuant, soft mass measuring about 15 cm. in diameter was found in the midlumbar region. No neurologic abnormalities were noted.

The blood pressure was 100 systolic, 80 diastolic. The temperature was 98.6°F., the pulse 90, and the respirations 20.

Examination of the blood showed a white-cell count of 11,300. The hemoglobin was 12.8 gm. per cent. The urine was negative. A blood Hinton test was negative, and a blood Wassermann doubtful. A lumbar puncture showed initial pressure of 120 mm. of water, with normal dynamics. Forty centimeters of clear fluid was withdrawn, which contained 3 white cells and no red cells per cubic millimeter; the total protein was 24 mg. per 100 cc., and the gold-sol curve 0000000000. A Wassermann test was negative. Pressure on the tumor gave no rise in the manometer.

Roentgenograms of the spine showed destructive changes in the dorsal portion of the spinous process of the fourth lumbar vertebra. This spinous process was enlarged and appeared to extend into the area of the fourth lumbar vertebra. There was no evidence of involvement of the neural arch, aside from the spinous process. The fourth lumbar vertebra was intact. An air myelogram with the air column poorly outlined in the lateral but clearly visible in the anteroposterior view. It was visualized only below the level of the fourth lumbar vertebra. The nerve sheaths were not filled. The cul-de-sac extended to the level of the second sacral segment and was normal in appearance. There was failure of closure of the spinal canal below the third sacral segment. No connection could be seen between the spinal canal and the mass posterior to the sacrum on the right side.

On the tenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. JAMES B. AYER: We are not told at what levels the lumbar puncture and the air myelogram were done.

DR. JOST MICHELSEN: They were both done at the same time. The needle was put in the interspace between the second and the third lumbar vertebra.

DR. AYER: Apparently there were two destructive areas, one in the lower sacral region and one in the spinous process of the fourth lumbar vertebra. Perhaps we should see the x-ray films.

DR. LAURENCE L. ROBBINS: These films were taken at the time of the air myelogram but with a different technic from that which would best demonstrate the soft-tissue mass. - I think we can make it out in this area. It apparently extends from about the posterior margin of the spinous process of the second lumbar down to approximately the second sacral segment. There is definite destruction of the spinous process of the fourth lumbar vertebra, which is apparently at about the center of the mass. I do not believe that this is a congenital anomaly, but rather a destructive process. So far as the air myelogram is concerned, it is not a satisfactory examination. I do not see any evidence of an inflammatory process encroaching on the spinal canal. There is evidence of congenital anomalies. The sacral hiatus is larger than usual, and there is incomplete fusion of the laminae of the first sacral segment, as well as an anomaly in the development of the articular facets of the third lumbar vertebra; but these things are of no practical importance.

DR. AYER: In the transcription it says that the air column stopped below the fourth lumbar vertebra. Is that your interpretation?

DR. ROBBINS: As I said before, the air myelogram was unsatisfactory; but I think that there was air all through the lumbar canal. The only way one could be sure would be to stereoscope these films in the anteroposterior view.

DR. AYER: Then the dogmatic statement "It was visualized only below the level of the fourth lumbar vertebra" is not borne out.

DR. ROBBINS: That is someone's opinion who had the opportunity to stereoscope the films. I should think there was air going up to the first lumbar vertebra.

DR. AYER: A good deal depends on this point, and I should like to say that the experience of some of us with air myelograms has not been entirely satisfactory. I prefer lipiodol. On the other hand, the members of a good many other clinics believe that they can outline a disk, which is something smaller than what we have here. So there is a difference of opinion in the interpretation of air myelograms.

We are told that the physical and neurologic examinations were negative, except for a lump the size of a grapefruit in the midlumbar region. Therefore discussion must center primarily on this mass. It was said to be cystic and fluctuant, and there was no pain connected with it, except when she bent her back. It enlarged rapidly, although we need not assume that its growth was limited to three months — perhaps eight months is a more reasonable estimate. As no note is made we may perhaps assume that the mass was neither tender, discolored nor warm to touch. Nor are we told whether it was attached to the skin or deep structures.

From the evidence, I think we can safely say that we are concerned with a rapidly growing mass situated slightly to the right of the midline in the low lumbar region, which contained fluid but was non-inflammatory, and was not accompanied by gross destruction of the vertebrae. Therefore, we can eliminate both pyogenic and tuberculous abscess, and also cancer originating in a vertebra. Tumors such as sarcoma and neurofibroma are firm and resilient, not primarily cystic, and may also be eliminated. By far the commonest fluctuant mass in this region is the meningocele, and the description given suggests this, although I miss the presence of the characteristic dimpling of skin and lanugo hair so characteristically seen. Nor is it likely that a meningocele, and even more likely a meningomyelocele, would be present with no disturbance of nerve function, particularly weakness and deformity of feet and bladder incontinence. Nor was there the characteristic lumbar defect in the spine. Nor was there fluid in this mass that connected with the subarachnoid space. I am forced to consider the embryonal tumors that occur in this region. Chordoma, which I believe is always firm and gives a characteristic x-ray picture of wide, clear-cut destruction of the sacrum, seems unlikely. But dermoid cyst and perhaps lipoma seem to answer the characteristics given. Both are associated with imperfections in the spine.

Was the spinal canal invaded? From the original interpretation of the air myelogram we are led to believe a block existed at the level of the fourth lumbar vertebra, but review of the films by Dr. Robbins fails to confirm this interpretation. Certainly there was no clinical evidence of involvement of the cauda equina, and yet we have often seen the lumbosacral canal filled with tumor — especially lipoma — without clinical evidence of its presence.

I therefore believe that the diagnosis that best fits this condition is a dermoid cyst, probably but not

necessarily with attachment to the meninges through the imperfect spine; lipoma is my second choice.

DR. MAURICE FREMONT-SMITH: May I ask whether cold abscess starting in the spine might not make this picture? You mentioned it, but you then hastily discarded it.

DR. AYER: I threw it out rapidly and did not give all the reasons. I think it is fair to assume that the mass had been there for eight months and, if tuberculous, should have shown more spinal destruction than it did. Does not Pott's disease start from the body rather than from the spinous process? Nor do I remember seeing it in the lumbosacral region. There was no fever. A sister had tuberculosis, but not the patient. Perhaps I threw out tuberculosis too nonchalantly but I do not believe that it is likely.

DR. ROBBINS: Is destruction of the spinous process frequent in lipoma or dermoid?

DR. AYER: Not in lipoma. In dermoid cysts, however, I believe that there are rests in the spinous processes as well as in the lateral masses. That is a point in embryology of which I am not sure.

DR. ROBBINS: Yes, I think there can be; but the thing that is impressive here is that it appears to have been a destructive process and not an erosive one.

DR. AYER: That is the weak point in the argument.

DR. ROBBINS: I should expect to see erosion of the spinous process.

DR. AYER: I rather wanted to have it a developmental defect. Perhaps it is unreasonable to say that I still wonder if it could have been originally a developmental defect because of the other anomalies that you have demonstrated. If I could have that leeway it satisfies me. Certainly an osteomyelitis starting there would not give this picture.

DR. ROBBINS: It could give that appearance in the spinous process.

DR. AYER: Yes, but hardly the rest of the picture, with the normal temperature and so forth.

DR. BENJAMIN CASTLEMAN: Dr. Kubik saw this patient before operation.

DR. CHARLES S. KUBIK: I do not remember the case well except that I missed the diagnosis. Perhaps Dr. Michelsen remembers it.

DR. MICHELSEN: Several points were not brought out in the summary that perhaps would have been of some value to Dr. Ayer. First of all, the size of the tumor increased on straining, sneezing and coughing, which made it fairly evident that the tumor contained fluid; but it did not transilluminate. There was also some tenderness to palpation.

It was decided to do an air myelogram not so much because we were hunting for an obstruction or a tumor in the spinal canal, but because we wanted to find out whether the mass was connected with the subarachnoid space. When this decision was made the destruction of the spinous process of the fourth lumbar vertebra had not been reported. The first x-ray films were read as negative.

On biopsy of the tumor a large amount of greenish pus was obtained and a small piece of bone was found at the bottom of the abscess.

CLINICAL DIAGNOSIS (preoperative)

Tumor of lower back (? hemangioma).

DR. AYER'S DIAGNOSIS

Dermoid cyst?

Lipoma?

ANATOMICAL DIAGNOSIS

Tuberculosis of spinous process of fourth lumbar vertebra.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The material we received showed caseous tuberculosis.

DR. MICHELSEN: After the diagnosis of a cold abscess was established, Dr. George W. Van Gorder was called in consultation. He stated that he had seen a similar lesion in that location, but that the condition was extremely rare. A detailed clinical checkup revealed that the patient had incipient tuberculosis of the lungs, and she was discharged to a tuberculosis sanatorium.

DR. AYER: The "wheezes" meant something after all.

CASE 30062

PRESENTATION OF CASE

A sixty-three-year-old tool inspector entered the hospital because of severe pain in the anterior chest of four months' duration.

The patient was in good health until about ten months before entry, when he developed a severe, dry cough and "bronchitis," which caused nausea and occasional vomiting. The cough persisted and was productive of small amounts of white mucous material. Syrup of hydriodic acid gave no relief. There was no hemoptysis, fever or night sweats. Shortly after the onset of the cough, his voice became hoarse, and gradually became worse, until on admission he could only whisper.

Four months before admission he experienced the sudden onset of a sharp, stabbing, substernal and epigastric pain, most pronounced after coughing. It recurred as often as six times a day and was occasionally made worse by deep inspiration. The pain was controlled by medicine that contained a "lot of codeine." Two months before admission he noted progressive weakness of the arms and legs. He had difficulty in keeping his balance and in walking and fell on an average of four times daily. There was urinary urgency without other urinary symptoms. Shortly thereafter he developed constipation, followed by periods of fecal incontinence, occurring about twice a week. There was no distention or

melenia. One month before entry he developed exertional dyspnea without orthopnea or paroxysmal nocturnal dyspnea. Two weeks before admission he felt as though he had gone to sleep from the chest pain. He attributed this to too much codeine since after omitting the drug this disappeared to some extent. His chest pain also decreased in severity. Nevertheless he was forced to give up his job. His appetite had remained "perfect," but there was a weight loss of 30 pounds in the six months preceding entry. He developed several boils.

Physical examination showed a moderately emaciated, slightly dyspneic man who coughed occasionally and spoke in a whisper. The skin was normal. There were a large ecchymotic area over the right knee, and an area of redness, swelling and ulceration over the left wrist. A fluctuant furuncle was present on the left hand. The tongue displayed a coarse tremor. The gag reflex was active. The trachea deviated slightly to the right. There was slight tenderness below the angle of the right scapula. A friction rub was heard in the right axilla. The diaphragmatic excursion was limited. The border of cardiac dullness was 10.5 cm. from the midline in the sixth space. The sounds were of normal quality and regular. The pulmonic second sound was greater than the aortic. There was a slightly tender mass in the epigastrium according to one observer, and no masses or tenderness according to another. Rectal examination was negative. Neurologic examination showed hyperactive patellar and ankle jerks, unsustained ankle clonus bilaterally and weakness of both lower extremities, more noticeable on the right. The upper extremities were weak. There was atrophy and wasting of all muscles of the extremities. The vibratory sense was diminished in the toes and ankles, and the position sense was absent in the toes. Hypesthesia and hypalgesia extended to the level of the umbilicus on the left, and to slightly lower than this on the right. The touch sense appeared to be intact. Laryngeal examination was unsatisfactory. The left tip of the epiglottis was ulcerated. The arytenoids and the pyriform sinuses were swollen and reddened. Both arytenoids moved, but the cord could not be visualized.

The blood pressure was 168 systolic, 92 diastolic. The temperature was 102.6°F., the pulse 82, and the respirations 28.

Examination of the blood showed a red-cell count of 4,400,000, with 10.5 gm. per cent of hemoglobin. The white-cell count was 11,750, with 78 per cent neutrophils. There was the slightest possible trace of albumin in the urine. The stools were guaiac negative. A blood Hinton test was negative. The vital capacity was 35 per cent of normal. No sputum examination was recorded, but a smear of the gastric contents showed no tubercle bacilli.

X-ray examination of the chest showed a large, coarse, nodular miliary process involving both lungs (Fig. 1). In addition there were plaque-like areas

of increased density in the central portion of the left chest and in the upper lung fields. At the apices, honeycombing and fibrosis were seen surrounding a few small cavities. The heart was enlarged, and the aorta moderately tortuous. Diaphragmatic motion was limited, and the costophrenic angles were obliterated. A gastrointestinal series and a barium enema were negative. X-ray films of the dorsolumbar spine and pelvis showed a destructive process involving the inferior aspect

DIFFERENTIAL DIAGNOSIS

DR. MAURICE FREMONT-SMITH: This is the case of a sixty-three-year-old man who had apparently been in good health until ten months before entry, at which time he developed cough and hoarseness. Bronchiogenic carcinoma is the first thing to think of when at this age a man's illness begins with cough. He might have had a primary bronchiogenic carcinoma with metastases into the other lung and

FIGURE 1. Roentgenogram of Chest.

of the body of the fourth dorsal vertebra and the upper aspect of the body of the fifth dorsal vertebra, with involvement of the disk. In the anteroposterior view there was a questionable soft-tissue mass surrounding these vertebrae. No other evidence of a destructive process was seen. A lumbar puncture gave an initial pressure of 270 mm of water; 10 cc of clear colorless fluid was withdrawn, the final pressure being 110 mm. The fluid contained 47 red cells per cubic millimeter, but no white cells. The total protein was 63 mg. per 100 cc. The gold-sol curve was 0000122100. The level at which the needle was inserted is not stated in the record, but there was no evidence of blockage.

The temperature remained about 103°F. The patient became more confused and delirious, and died on the eleventh hospital day.

with a metastatic process in his spine, causing cord changes. Against this is the fact that it is very unusual for a metastatic carcinoma in the lung to form a cavity. Such an explanation would also leave out entirely the changes in the larynx, and if one takes those into consideration the other possibility, which seems by far the most likely, is tuberculosis, which not infrequently becomes active in old age.

This patient apparently had widespread tuberculosis of both lungs and a metastatic tuberculous process in the spine, with a Pott's abscess and laryngeal tuberculosis. He could, however, have had primary laryngeal carcinoma with metastases or primary carcinoma anywhere in the body with metastases. It should be noted that intrinsic carcinoma of the larynx — that is, carcinoma of the vocal cord — does not metastasize rapidly and the

metastases do not occur below the clavicles. Extrinsic carcinoma of the larynx, like any other carcinoma, can metastasize to any part of the body.

The fact that this man had an ulcer on the epiglottis is greatly in favor of tuberculosis. If this process was tuberculous, it is surprising that the patient did not have pain on swallowing and that pain in the larynx was not mentioned.

It is worth while to emphasize two things before going on with the differential diagnosis. In the first place, one is apt to forget that pulmonary tuberculosis can start with hoarseness and not with cough. Secondly, just as we have had impressed on us during the last few years that chronic edema of the legs is not always cardiac, and that a large proportion of patients have edema from other causes, frequently from varicose veins, so too in dealing with chronic dyspnea one is not apt to realize that the dyspnea may come not from the heart but from other trouble in the thorax.

This man also had injury to the cord. Manifestly the pyramidal tracts were involved, with increase in the reflexes and a little clonus, as well as the posterior tracts, with sensory disturbance. The thing that disturbs me is that the muscles of all the extremities were said to be atrophic. The patient could have had atrophy of the legs from the cord injury, especially if the anterior-horn cells were injured by compression. To explain the atrophy of the hands a cervical lesion must have existed, or one would have to premise a generalized disease, such as myotrophic sclerosis, which is farfetched.

Did the boils indicate that there was a secondary staphylococcal blood-stream infection on top of the primary infection, which I believe was tuberculosis? I have gone ahead without looking at the x-ray films and may have to modify some views when I see them.

DR. LAURENCE L. ROBBINS: There is a rather sharply defined mottled process completely involving both lungs. I am not at all sure that I can be positive about the presence of cavities. With this type of process it is a rather difficult decision to make, because numerous superimposed miliary nodules, when taken all together, give an impression of cavities. Certainly there are areas of rarefaction that do suggest small cavities. If there are cavities, I should have expected them to be higher in the right upper lobe.

The films of the spine show destruction and compression of the bodies of the fourth and fifth thoracic vertebrae. The disk spaces are not well visualized and there appears to be a surrounding soft-tissue mass.

DR. FREMONT-SMITH: Is it fair to ask whether this picture in the lungs was miliary tuberculosis on top of old tuberculosis of the lung?

DR. ROBBINS: It is hard to be sure that there was an old tuberculous process. It is a question to ask, but I do not see how I can answer it. There are

certain things, such as a thickened pleura, that may be the result of an old process. The miliary process can be due to several different things from the x-ray standpoint.

DR. FREMONT-SMITH: How about silicosis?

DR. ROBBINS: It might be, but it is atypical. Miliary malignant disease can give a similar x-ray picture.

DR. FREMONT-SMITH: Would you say that it could not be miliary tuberculosis?

DR. ROBBINS: No; that is probably the commonest condition to produce such an appearance.

DR. FREMONT-SMITH: I think that the evidence, including the laryngologic examination, the destructive process in the spine, the soft-tissue mass and the x-ray picture, is in favor of a diagnosis of tuberculosis. The sputum was not examined. The gastric contents were said to be negative. I am rather dubious about the value of gastric contents unless the material is put into a guinea pig, in which case one gets a reasonably accurate diagnosis. That should always be done in a case of probable pulmonary tuberculosis that is not diagnosable by sputum examination. I shall rest my case on the diagnosis of tuberculosis.

DR. BENJAMIN CASTLEMAN: Dr. Means, you saw this patient, will you give us your impression?

DR. J. H. MEANS: Our line of reasoning followed much the same course as that of Dr. Fremont-Smith. We were confronted with a spinal lesion, — compression of the thoracic cord with certain neurologic manifestations resulting therefrom, — and this peculiar lung lesion, with fever. We thought that it was either cancer or tuberculosis, but we did not know which. I tried to pin down the radiologist, but did not succeed. I asked him the following questions: "Can you say definitely that the spinal disease is or is not tuberculosis? Can you say definitely that the spinal disease is or is not malignant? Can you say definitely that the lung lesion is not miliary tuberculosis?" He wrote in answer to all my questions, "No"; but he did favor tuberculosis.

DR. FREMONT-SMITH: Might I ask Dr. Kubik to say a word about my comment on the neurologic findings — that is, how to account for the atrophy of the arms and legs.

DR. CHARLES S. KUBIK: There is definite evidence of cord compression, because of the changes in the leg reflexes and the sensory impairment below a certain level, but I do not believe that we know enough about the atrophy in the arms to be able to say anything about it. That might have been due to the generalized weight loss.

DR. JOST MICHELSEN: Dr. Robbins, do you think the involvement of the disk is in favor of tuberculosis rather than of malignant disease?

DR. ROBBINS: Yes, if I could be sure the disk was involved. A study of that area of the thoracic spine is particularly difficult because of the curvature,

d I am not sure that it is not simply a process of overlapping shadows rather than of active destruction of the disk.

CLINICAL DIAGNOSIS

Carcinomatosis of lung and spine?
Miliary tuberculosis?

DR. FREMONT-SMITH'S DIAGNOSES

Miliary tuberculosis, involving lungs, spine and larynx.
Healed pulmonary tuberculosis.

ANATOMICAL DIAGNOSES

Miliary tuberculosis of lungs, spine, meninges, larynx and kidneys.
Healed pulmonary tuberculosis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this man showed a widespread miliary tuberculosis, with a cavity 4 cm. in diameter in the right upper lobe. There was tuberculosis in practically every organ in the body. The fourth and fifth dorsal vertebrae, with the intervening intervertebral disk, were involved in a large tuberculous abscess. We were not sure on gross examination whether there was actual invasion of the meninges, but microscopically there is not only involvement of the meninges locally but also involvement of the ependyma of the ventricles, apparently an ascending infection. There was tuberculous ulceration of the larynx.

COMPARATIVE VALUES

WE Americans, with our mixed racial strains, our varied hereditary characteristics drawn from many lands and many ethnologic types, have attained at least one common factor — acquired, perhaps, from an environment that has been overly generous to us. We are generous to others, particularly if a call is made in a way to appeal to our open, warm-hearted, somewhat erratic and at times exceedingly sentimental emotions. If anyone tries to take what belongs to us, we fight at the drop of a hat; but if the emotional floodgates are opened, we give it away. This characteristic is simply illustrated by the old story of the tough character and the flower girl: "Don't cry, little girl. I'll buy your — — violets."

The journalistic gentry learned long ago to pluck the pulsing heartstrings of their public. Crime may go unpunished and injustice may pile unnoted upon injustice, but let some columnist mention the fact that a cripple needs a wheel chair or a veteran requires a wooden leg, and the checks float down like a kindly Christmas snowstorm. The need must be specific and emotionally presented, the beneficiary must be an individual with a personality of sorts, but the response is hundredfold, if it is only a new wig that is requested.

Publicity (or propaganda, if you will) is one of the most powerful instruments that we possess, and a great trust — to use it well and wisely — is put into the hands of those who guide it.

We have seen recently an example of its effectiveness, regardless of how wisely or unwisely it was in this case directed, or whether it was initiated in the best interests of the public. A child suffering from an admittedly incurable chronic nephritis (presumably nephrosis) has had life maintained, or at least has been treated, by the administration of large quantities of blood plasma, the fluid for lack of which many an American soldier may be doomed to die this summer unless the American public is re-awakened to its duty. A Boston newspaper, taking up the cause of the child, has obtained enough plasma from local donors to guarantee, it is said, some prolongation of life for the patient.

If journalism will now turn its considerable powers toward obtaining enough blood donors for the Red Cross to make up the deficit of plasma that threatens the effective treatment of our wounded soldiers and sailors, we shall congratulate it most wholeheartedly on the gesture it has made in behalf of the child.

TRENDS IN PNEUMONIA MORTALITY

Most physicians are greatly impressed by the improved outlook with respect to pneumonia. This favorable impression is derived from the better prognosis in individual cases of bacterial pneumonia under modern chemotherapy. Some recent studies, however, indicate that the trend in pneumonia mortality may be changing for the worse, although

it is hoped that these changes will be only temporary.

A recent survey by the United States Public Health Service¹ indicates that since the summer of 1937 pneumonia mortality has markedly declined. An average of the mortality rates for the five-year period 1938-1942 compared with that of the five preceding years showed a decline of approximately 40 per cent, and the decline occurred in all geographical sections of this country. The mortality from influenza and pneumonia for a group of ninety cities in the United States, however, was higher in the third and fourth quarters of 1942 and the first quarter of 1943 than it was in the same quarters of the three preceding years.

Epidemics of minor intensity occurred in five of the eight winters since 1935. Three of these epidemics — (1935-1936, 1936-1937 and 1940-1941) — were practically nationwide. The epidemics of the winters 1938-1939 and 1939-1940 were confined to four or five geographical sections of the country.

An increase in pneumonia mortality was also noted in the latter months of 1942 and the early months of 1943 among the industrial policyholders of the Metropolitan Life Insurance Company.² The Metropolitan statisticians noted a sharper than usual rise in the death rate from pneumonia during the winter of 1942-1943, which was much higher than the rise in the corresponding months of the previous year. They believe that this was due chiefly to an increase in the virus or atypical pneumonias, which fail to respond to sulfonamide drugs. They also noted that a large proportion of the fatal cases of the virus pneumonia occurred among young persons. Thus, in 36 per cent of the deaths from this type of pneumonia the patients were between fifteen and forty-four years of age, as compared with the usual figure of 18 per cent. Their data indicated that pneumonia during this period was two or more times as frequent in the Army as in the preceding year and that in some defense areas pneumonia was more than three times as frequent early in 1943 as it was in 1942. In spite of all this, the mortality was still 35 per cent lower than in the first quarter of 1938-1939.

Another interesting review of the public-health and economic aspects of pneumonia was recently published by workers of the Equitable Life Assur-

ance Association of the United States.³ They compared experience among a large group of industrial employees in the pre-sulfonamide years 1935-1937 with that for the period from January 1, 1939, to June 1, 1942. Most striking was the reduction in the case fatality rate in pneumonia from an average of 20.8 to 3.9 per cent in this short space of time. In addition there was a decrease in the total duration of illness from the modal (most frequent) period of thirty-eight days in 1935 to twenty-seven days in 1941. According to their calculations the lives of twenty-five thousand workers were saved annually, and in addition the loss of a million working days was prevented as a result of the shortening of the period of illness. These authors noted that the incidence of pneumonia increased appreciably during the period of study. They believe that factors such as congestion in industrial areas incidental to the war effort might have been responsible for this increase.

It is well known that deaths from pneumonia increase during periods when influenza is epidemic. Such an increase in pneumonia deaths was associated with the widespread epidemic of influenza in 1940-1941, although this increase was not of alarming proportions. Although the general upward trend of pneumonia mortality during the first part of 1943 did not continue throughout the year,⁴ another increase did occur during the latter part of the year as a result of the prevalence of influenza. In New York State, excluding New York City, the number of pneumonia cases reported for the week ending January 1, 1944, was 982.⁵ For the week ending January 2, 1943, only 397 cases were reported, and this compares with the 1938-1942 average for the similar period — namely, 358 cases. The reporting of cases of pneumonia is, of course, not accurate and is not required in many states. There is no doubt, however, that the number of primary pneumonias in Massachusetts has increased — perhaps in a similar proportion. In the large hospitals in Boston the great majority of these have been pneumococcal lobar pneumonia.

Whether further increases in pneumonia deaths will occur apart from the epidemic rise remains to be seen. At any rate these recent observations should dispel the feeling of complacency that has

been engendered by the individual successes due to improved therapy. Facilities are still available for pneumococcal typing in Massachusetts, but physicians are not availing themselves of these facilities to a sufficient extent. Many of the recent cases were of great severity, and a significant proportion of them were suitable for combined chemotherapy and specific antipneumococcus serum therapy. Physicians may well benefit from a greater use of the bacteriologic facilities that the Commonwealth and various communities offer to aid in the proper therapy of pneumonia.

MEDICAL EPONYM

SCHILDER'S DISEASE

This eponym refers to a form of encephalitis first described by Dr. Paul Schilder (b.-1886), while a teaching assistant of the Royal Psychiatric Clinic in Leipzig, in a paper entitled "Zur Kenntnis der sogenannten diffusen Sklerose: Über Encephalitis periaxialis diffusa [Contribution to the Study of So-called Diffuse Sclerosis: Encephalitis periaxialis diffusa]," which was published in the *Zeitschrift für die gesamte Neurologie und Psychiatrie* (10:1-60, 1912). A portion of the translation follows:

There is a diffuse affection of the white substance of the hemispheres in children that we are justified in regarding as a disease entity on the basis of characteristic macroscopic and microscopic findings in the brain. I propose for it the designation "encephalitis periaxialis diffusa."

The clinical picture of this disease is extremely variable. It follows a course which sometimes resembles that of brain tumor, sometimes simulates multiple sclerosis, or again resembles Heubner's diffuse sclerosis. We may suspect the existence of this disease if symptoms point compellingly to a widespread lesion involving both hemispheres. Attacks with the symptomatology of multiple sclerosis running a rapid course in youthful patients will likewise bring our disease to mind. The disease is a fatal one, with little tendency to remissions.

DEATH

SPALDING — Fred M. Spalding, M.D., of Brookline, died January 24. He was in his seventy-fourth year.

Dr. Spalding received his degree from Harvard Medical School in 1897. He practiced in Boston for many years and served as an intern and later senior ophthalmic surgeon and consultant to the Massachusetts Eye and Ear Infirmary. He retired from active service in 1924, but returned after the start of the war to give his service as an aid to the war effort. He was a member of the Massachusetts Medical Society, American Medical Association and American Ophthalmological Society. He was a former president of the New England Ophthalmological Society.

His widow, two sons and a daughter survive.

NOTICES

BOSTON MEDICAL HISTORY CLUB

There will be a meeting of the Boston Medical History Club in Sprague Hall at the Boston Medical Library, 8 Fenway, on Monday, February 21, at 8 p.m. Dr. Louis E. Phaneuf will speak on the subject "J. Marion Sims — Father of Modern Gynecology."

All interested persons are cordially invited to attend this meeting.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, February 15, at twelve noon.

Dr. Brainard F. Conley will discuss the Wagner-Murray-Dingell Bill. This proposed legislation (known as Senate Bill 1161 and House Bill 2861) has provoked much discussion in medical and hospital associations and is of interest to every physician.

Physicians are cordially invited to attend.

SUFFOLK CENSORS' MEETING

The censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, on Thursday, May 4, 1944, at 4:00 p.m. Applications must be received not later than February 15.

NEW ENGLAND PEDIATRIC SOCIETY

There will be a meeting of the New England Pediatric Society on Wednesday, March 8. The clinical presentation will be held at the amphitheater of the Children's Hospital, and all other events at Longwood Towers, Brookline.

PROGRAM

- 4:00 Clinical Meeting: Presentation of cases by members of the Children's Hospital Staff.
- 6:30 Refreshments.
- 7:00 Dinner.
- 8:00 Annual meeting.
- 8:15 Neurosurgical Problems of Childhood. Dr. Francis D. Ingraham.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

The regular meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore, Boston, on Wednesday, February 16, at 8 p.m. The topic for discussion will be "The Technique and Results of the Kenny Treatment." Miss Dorothy Fredrickson will discuss and demonstrate the Kenny technic. A council meeting will be held at 6 p.m., followed by an informal dinner in the Empire Room at 6:30.

All members of the medical profession are invited to attend this meeting.

ELECTROMYOGRAPHIC STUDIES OF MUSCLE DYSFUNCTION IN INFECTIOUS POLYNEURITIS AND POLIOMYELITIS*

MARY A. B. BRAZIER, Ph.D.,† ARTHUR L. WATKINS, M.D.,‡ AND
LIEUTENANT COMMANDER ROBERT S. SCHWAB (MC), U.S.N.R.§

BOSTON

THE similarity of clinical findings in acute infectious polyneuritis¶ and in poliomyelitis and the difficulties in differential diagnosis have recently been emphasized by several authors.^{1,2} The outstanding symptoms that are common to both diseases are motor weakness or paralysis and varying degrees of tenderness and pain in the muscles of the back and extremities. The distribution of the involvement is an important point in differentiation, for in poliomyelitis the typical weakness is segmental and asymmetrical in distribution, whereas in polyneuritis the extremities are usually symmetrically weakened, the most severe involvement occurring proximally. Minor sensory changes can usually be detected in cases of polyneuritis and the cerebrospinal-fluid findings with albuminocytologic dissociation are characteristic of this disease. The prognosis in poliomyelitis in the acute stage is uncertain, residual paralyses being frequent, whereas in polyneuritis residual palsies are rare. The progression of paralysis is also different in these diseases, for in poliomyelitis the weakness is maximal during the acute phase, whereas in polyneuritis there may be a gradual increase in the degree of involvement and a spread to new muscles late in the course of the disease. Further details of the clinical picture and pathologic lesions have been discussed in recent reviews.³⁻⁸

In view of the similarity of symptoms in these diseases, we have treated patients with polyneuritis with hot packs and have observed as effective relief of muscle pain and tenderness as we have in poliomyelitis. To elucidate further the similarities in the behavior of muscles, we have studied by electro-

myography the patterns of electrical activity in the affected muscles of a series of patients with polyneuritis. Comparisons have been made with similar recordings from muscles in poliomyelitis in an attempt to throw light on the problem of muscle spasm and other dysfunctions in these diseases. In some cases comparisons have also been made with the recordings from cases with traumatic lesions of peripheral nerve, since these give direct evidence of the electrical behavior of muscle during regenerative changes in nerve.

METHODS OF STUDY

Ten cases of infectious polyneuritis from the Neurological Service of the Massachusetts General Hospital have been studied during the acute and convalescent stages of the disease. These had the characteristic symptomatology already described, including albuminocytologic dissociation in the cerebrospinal fluid.

The affected muscles were examined for clinical evidence of tenderness or pain on stretching, and their functional strength was assessed by the usual manual tests. The electrical discharges from these muscles at rest and during active and passive motion were recorded by means of an ink-writing oscillograph. Surface electrodes were usually employed, but in some cases these were supplemented by coaxial needle electrodes inserted in the belly of the muscle. The details of the technic have been fully described.⁹ Comparisons have been made with similar studies on 10 patients with poliomyelitis and on others with traumatic nerve lesions.

RESULTS

Resting Muscles

The first series of electromyograms were recorded from resting muscles in positions of complete relaxation. No electrical discharges are recordable from normal controls by this technic under such conditions.^{10,11} In patients with polyneuritis, although the muscles were tender to pressure and stretching, spontaneous discharges were found only in the pres-

to the muscles, although the function of remaining motor units can be brought to the maximum by physical therapy.

It has been suggested that spontaneous discharges

FIGURE 5. *Simultaneous Activation of Opposing Muscles on Voluntary Dorsiflexion.*

The A tracings are from the anterior tibialis muscle, and the B tracings from the gastrocnemius. Simultaneous activation occurs in polyneuritis and poliomyelitis, but not in a normal control.

from resting muscles in polyneuritis, poliomyelitis and traumatic nerve lesions are a sign of a regen-

with improving motor power. The histologic features of regenerating axons after traumatic nerve lesions are well known. The degenerative changes in peripheral nerves in polyneuritis have been described, and to account for recovery it is natural to assume that regeneration of axons takes place. In poliomyelitis no primary lesions in the peripheral nerves are generally recognized, although the virus may enter the cord by passage up an axon after experimental injection.²⁶ Axonal regeneration is, therefore, not thought to account for the improvement in motor strength that usually occurs. We have noted, however, that paretic muscles have diminished electrical excitability as measured by strength-duration curves, and that as power returns the excitability improves. This indicates that there are relatively severe although reversible lesions, presumably in the anterior-horn cells, and that secondary axonal changes may also occur. The electrical discharges probably represent returning function in motor units, but, of course, reveal no evidence of the types of histologic change that are taking place. The microscopical appearance of the axons is probably quite different in all three conditions under discussion, so that the term "regeneration" when used to describe our observations implies only a recovery process.

The simultaneous activation of opposing muscles observed in polyneuritis and poliomyelitis might be thought of as a type of "inco-ordination," as described by Kenny.^{13, 14} This is not, of course, inco-ordination in its usual meaning of abnormal muscular control in cerebellar disease. We prefer to interpret it as disruption of reciprocal innervation. In some

cases this disorder is apparently related to pain, the antagonistic muscle involuntarily contracting to prevent excessive movement. In poliomyelitis and in regenerating peripheral nerves after injury, we observed synchrony of action potentials, indicating severe disorganization of reciprocal innervation. In traumatic nerve lesions this probably represents abnormal axonal regeneration. There may also be similar abnormalities in the regenerative processes in poliomyelitis, although histologic evidence of this is lacking.

SUMMARY AND CONCLUSIONS

Electromyographic studies revealed the following similarities of muscle dysfunction in infectious polyneuritis and poliomyelitis: muscle tenderness and paresis are characteristic of both diseases, and the electrical abnormalities in both cases are correlated with weakness rather than with sensitivity. partially paralyzed muscles on stretching show hyperirritability, which can be relieved by hot fomentations; even at rest, parietic muscles are hyperirritable, discharging electrical potentials characteristic of regenerating motor units, and reciprocal innervation is frequently disrupted in polyneuritis and poliomyelitis, with resulting simultaneous activation of opposing muscles — this abnormality is probably secondary to painful motion.

The disorganization of reciprocal innervation is not so severe in polyneuritis as in poliomyelitis, for the simultaneous activation of opposing muscles in the former disease is not characterized by synchrony of component discharges.

GERIATRICS: THE MEDICAL CARE OF THE ELDERLY*

ROGER I. LEE, M.D.

BOSTON

THE whole subject of geriatrics is relatively new. It can be compared to pediatrics, which was a blossoming subject when I was in medical school, but has now come to full fruition. The situation of the elderly has changed a great deal, because whereas a few years ago the average age of death was in the forties, a child born in the year 1943 may be expected to live to at least sixty-four years of age. The interesting thing is that the advances of medicine and public health have been directed almost entirely toward the early age group — that is, the age in which there has been improvement in mortality and morbidity statistics.

The man of forty to sixty-five lives no longer than he did fifty years ago, and there is a certain amount of evidence that he is no healthier. In other words, the present program of preventive medicine is enabling a great many people to live to sixty-five years but is not promising them anything when they do. It seems only fair that if they are to live as long as this, life ought to be made happier and healthier for them than it now is. Old age has been what one might call tolerated by the medical profession and by the public in general. No one is enthusiastic about old age. Certainly elderly people themselves are not particularly enthusiastic about it. In general, society has taken a negative and an entirely defeatist attitude toward old age. When the elderly are dead, society decrees a costly funeral and flowers.

As long as this negative, defeatist attitude continues, nothing is going to happen. Of course, part of this situation has been due to the fact that many of those who were looking for the alleviation of old age were not doing it from a medical or scientific point of view. All the folklore, all the tales about those who were interested in the elixir of youth — Ponce de Leon, in trying to find the Fountain of Youth, Ulysses, Sinbad the Sailor — show that these people were interested in only one thing, the re-creation of their sexual capacities, and not in the health of old age. This attitude has, of course, damaged the whole movement of geriatrics, when men are interested only in sex rejuvenation, and women only in keeping their charm, and, it will be noted, not usually their fertility.

I have no intention of discussing the damaging diseases of older people, — by which term is meant all those older than fifty-five and certainly those older than sixty, — such as advanced cancer, apoplexy and degenerative heart disease, about

which at that stage nothing can be done. It may be said in passing that it is only by the study of the advanced stages of disease that one can gradually get back to a study of the origins of the disease, therefore, a certain amount of attention paid to cancer, even advanced cancer, apoplexy, degenerative heart disease or what not may bear fruit in the long-distant future. A few simple diseases, however, are particularly frequent in old age. Gallstones, for example, increase in frequency with advancing birthdays, and it is likely that if people lived to be one hundred and twenty they all would have gallstones. Certainly, autopsies performed on people of eighty or over show almost uniformly the presence of gallstones. This may have some effect on the present attitude toward the diet of older people, which is discussed below.

Another illustration of the diseases of old age is diverticulosis, which is increasingly frequent with advancing age. X-ray studies show that nearly all people over sixty have a few diverticula. This condition may lead to an inflammation of one of the diverticula — the clinical entity known as diverticulitis.

Inflammation of the intestines also seems to be on the increase in the elderly. Appendicitis is usually thought of as a disease of young people, and it is certainly extremely common in that age group, but it again becomes frequent after the age of sixty. Since gallstones occur in elderly people, it is often taken for granted that a stomachache is due to them or to diverticulitis, but a passing plea must be made for the consideration of appendicitis, which often takes the gangrenous form in people over sixty.

As the aging process, like the growing process, has been studied, it has been found that to keep the machine running, just the same as to keep the machine growing, there must be food and nourishment. Probably one of the greatest mistakes, by and large, has been to let the aged select their own diet, the latter depending on the condition of their teeth, whether they could chew it or not, depending perhaps on their pocketbooks and on the convenience of getting the food. It is certain that whereas in the family circle great attention is paid to the food for growing children, little attention is paid to the food for elderly people, even though they need it to continue their somewhat waning energies. To repeat, probably the most important thing in elderly people is the administration of the proper food in adequate quantity and quality. Here may be seen par excellence the necessity of giving vitamins.

*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 11, 1943.

For many years, I was rather an off horse concerning many of the vitamins, and it has only been in the last few years, when vitamin concentrates have become available, that I have been able to convince myself of their value, particularly in people with a restricted diet, and particularly with the aged. On the subject of vitamins, the elements of the vitamin B complex are particularly indicated in older people, for two reasons. One is that the vitamin B complex — this refers to most of the factors in that complex — is easily used up in the human economy, in marked contrast to vitamins A, C and D, and has to be replaced frequently, one might say continuously. Furthermore, as a person gets older his carbohydrate intake is apt to be increased, and he needs certain components of the complex for catalysts of the carbohydrates to assist digestion.

In older people — perhaps because they are subject to two conditions, one of them gallstones and the other diverticulosis — it is the common experience that the administration of a high amount of fat and of roughage is often contraindicated. The difficulty with fats may have some relation to the existing gallstones, or it may have a simple relation to the fact that fats are much more difficult to digest than are any other food elements.

In connection with diverticulosis, it is usually evident that elderly persons do not take the high-roughage diet, which is so fashionable nowadays and which middle-aged women take with such enthusiasm. Such a diet often disturbs the digestion as people get to sixty and beyond, and it is usually advisable to restrict, at least moderately, the amount of roughage that goes into the diet.

I used to be one of those who objected strenuously to many of the digestive remedies that at one stage were so popular. As one studies elderly people, one appreciates that one of the things that does occur in them is the diminution in function or secretion throughout the body, and the same is true of the digestive tract. As one practices clinical medicine more and more, one changes one's ideas a little, and with the elderly I have entirely changed my ideas about the efficacy of some so-called "digestive assistants," foremost of which perhaps is the addition of hydrochloric acid to the diet. It is well recognized that as a person gets older he is apt to have less and less hydrochloric acid in his stomach and has more and more gas, and it can be shown clearly that if the reaction of the food and of the material in the stomach is changed, other changes are produced all the way down the intestinal tract. Hydrochloric acid is mentioned merely as one of the possible adjuvants to the therapy of older people, because it represents a principle of supplanting or supplementing the juices and functions that have been reduced.

At one time, I was scornful about the use of pepsin. I have found, however, that in the aged, as with hydrochloric acid, pepsin and even the pan-

creatic extract are often of real value. The same is true of the administration of bile, as bile salts or otherwise. These substances are not as a rule highly effective among younger people, but toward the age of sixty there is usually a deterioration in the secretions of the body or a reduction in their total amount.

It is certain that older people are much better off without the laxatives that have been given so widely in the past. They now seem to be reserved almost wholly for the elderly, the argument being, as always, "It doesn't make any particular difference." But it does make a difference, and the intestinal tract can be helped by the same procedures that are used in younger people and by the same attempts to do without laxatives. I am a great believer in mineral oil, but realize that since it absorbs vitamin A, the latter may have to be replaced. I am also a firm believer in colonic irrigation for elderly people, done about once a week.

Just as I have discussed the gastrointestinal system, one can take the other systems and go over them with the same point of view. There is one system that comes to the mind of everyone who deals with older people — namely, the endocrine glands.

Potassium iodide, which is so often given for arteriosclerosis in older people, is prescribed for them by most physicians simply because it seems to agree with them. As a matter of fact, iodine is an important part of the thyroid secretion, and the latter is stepped up by the addition of iodine to the thyroid nucleoprotein. Furthermore, many elderly people with deficient thyroid secretion are greatly invigorated by the judicious administration of thyroid.

The disturbances of the endocrine glands are not always the disturbances of diminution, because after sixty toxic goiter is seen, and sometimes it persists and creates a puzzle in diagnosis. It is not necessary, however, to do a metabolism test on every old man who has a rapid heart and is losing weight just because one such gentleman happened to have an exophthalmic goiter and was cured by a subtotal thyroidectomy.

By all odds, the most frequent disturbance in the thyroid gland is the diminution in the quantity or quality of the thyroid secretion. Glycosuria — not to be confused with true diabetes — is frequent in elderly people but often requires no treatment. Elderly men are naturally enthusiastic about the possibilities of testosterone. Some of them have been through the various operations for rejuvenation, including the substitution of goat glands, and have not been made particularly happy except, perhaps, psychologically at times. The modern endocrine hormones are decidedly potent, but they are to be used with a certain amount of discrimination, just as are the female hormones, which are so useful in the menopause and subsequently. These two sets of hormones are often helpful in the elderly, but not so much from the personal view of the man

who wants to be a Don Juan or the woman who wants to be a Venus as from that of the general condition and general health.

No thoughtful person who considers the subject of diseases of the prostate gland fails to realize that although much benefit has resulted from the surgical approach, the final solution will probably be the taking of a pill, either by mouth or by injection. When it is discovered how and why the prostate gland grows old, they will be given substances that will control the prostatic hypertrophy and render surgical treatment unnecessary. But this development is still in the realms of wishful thinking and of experiment.

The most frequent causes of death in the elderly are of course the degenerative diseases of the heart, blood vessels and kidneys, and this is the field in which one would like to make progress. It is true, however, that at the moment there is no method and no clue for lessening the mortality of these diseases.

Dr. Timothy Leary has made out an excellent case for the damaging effect of cholesterol in premature and devastating arteriosclerosis. He calls this effect atherosclerosis. There is a certain amount of evidence of one sort or another that supports this view. On the other hand, a good deal of the experimental work now being done is based on the influence of certain diets on rabbits and other animals. Rabbits are herbivorous creatures, whereas man will eat anything, including meat. Of course, when cholesterol, which is an animal fat, is added to the diet of a rabbit or indeed to other animals there may be some findings that are not easily transferred to man. There is no indication that Italians, who live on vegetable fats and oils in contrast to Anglo-Saxons, who live on the protein ones, grow old any more gracefully or have any fewer diseases than the rest of mankind.

As a matter of fact, it is too bad that the real answer cannot be found. It is fashionable to state that degeneration of the heart and blood vessels is due to the wear and tear of life. But if this matter is closely examined it will be found that certain people develop conditions or diseases the explanation of which is, "No, that isn't wear and tear; that is just rust."

Those who are interested in general hygiene tell us that it is a matter of this, that or the other thing. But when it comes right down to it, health seems to have a great deal to do with the care with which one picks one's ancestors. If this is done with discretion and they had normal cardiovascular systems, they are apt to transmit them to their descendants.

It is also necessary to assume as a part of the treatment of old age that there is something else to live for than negative security. It is perfectly true that the occupants of old men's or old women's homes live a long time, or at least live almost indefinitely, but they live rather as vegetables than as real human beings.

In order to pass one's old age gracefully, pleasantly and helpfully, one must have some sort of objective in life, and that objective should be a little bit more than outliving somebody else. As one observes older people, however, it is interesting to see that this is often the dominating factor in their lives. It may be a son-in-law who is particularly despised; or the attitude may be that of two brothers who checked off people as they died, hoping, distinguished as they were, to be the oldest twins ever graduated from Harvard College when they passed away.

I saw a gentleman of ninety one day when he was in high spirits. He was a physician and a member of the Old Vienna Club. He rubbed his hands gleefully and said, referring to a lifelong friend, a fellow member of the club, "He isn't going to last long."

I mention these things not to cause amusement, but because there is some value in the psychological treatment of older people. They must have some incentive to live or they will, at times, literally curl up and die.

In 1914 a ninety-five-year-old lady called her family together and said: "I am an old woman, and I am going to die. I have taken to my bed." She also announced that she would give her brooch to so-and-so and her cameo to so-and-so. About that time World War I started and she became quite interested in reading the papers. The family rather neglected the nice old lady upstairs. Since they usually read the paper downstairs first, she would go downstairs and get the paper, and she became quite interested in how the war was going. She lived along all four years of the war, and then came the Treaty of Versailles. She then said that she did not think that the war had really proved anything. So she went to bed, summoned all her relatives and again said, "Now, I am going to die." But they said: "You can't put that over on us. You said that four years ago." But this time there was no World War I; there was nothing for this woman to live for, and she did what most older people do. It took her three weeks to run down, — it usually takes that long when old people take to their beds, — and that time she did die.

What I am pleading for is that older people must be treated psychologically as well as physically. I am no psychologist or psychiatrist, but when I went into the practice of medicine in Boston there was in practically every house on Beacon Street a room upstairs in which some old person lived and was never allowed to leave. People put lace caps on them or did something or other, and they vegetated there until they died. But one does not see that any more. The older people are not standing for it, and this is the first step in the treatment of geriatrics. These older people are being got out. Although I do not approve of their picking up gigolos and going dancing, at the same time a certain amount of that sort of thing is to be recommended. The family and the physician must have a certain amount of interest in older

people. They must have attention. Just today, one of your distinguished members came up here and talked in such an undertone that my old ears could not hear him, so I naturally switched off my attention. The younger people must talk loud enough so that we older ones can hear what they have to say.

I can do no better in closing than to tell a story concerning Dr. Stephen Smith, who was the first health officer of New York City. Because he was a health officer, he thought he knew all the principles of health and of righteous living. He was one hundred years old, and some people wanted to give him a dinner. I thought that was a terrible outrage. Then I thought, well, after all, he is a hundred years old, and he won't live long; he may have a good time, so why don't they do it? It may kill him, but what of it? They gave him the dinner.

Because of my curiosity about these things, I went over and talked to Dr. Smith, because I wanted to

ask him about his ancestors. He had any number of ancestors on both sides of his family that had lived to be one hundred or one hundred and five. He didn't like my question very much. Then I saw his daughter, who had given up her whole life to looking out for this old man. She was a spinster of about seventy-five winters, and she was not particularly communicative. I said to her: "Now, when people live to be old, there is always some reason for it. They either don't smoke or do smoke; they either don't drink or do drink; and they either drink in the morning or in the evening, or something of that sort. What do you think about that?" But, she would not bite on that. Finally, I said to her, "What do you give your fine old father to eat?" There was a little smile that came over her face, and she said, "Well, I feed him mostly on milk, whiskey and flattery, and the last two seem to be the more important!"

264 Beacon Street

PURPURA ANNULARIS TELANGIECTODES*

Report of a Case

SVEN M. GUNDERSEN, M.D.,† AND JAMES G. BENNETT, M.D.‡

HANOVER, NEW HAMPSHIRE

CASE REPORT

PURPURA annularis telangiectodes, first described by Majocchi,^{1,2} in 1896, has appeared infrequently in the American literature. In 1915, MacKee³ published a comprehensive review of the subject, along with extensive observations of a case of his own. In 1929, Scholtz⁴ reported a case and reviewed 7 cases reported since MacKee's original review. In 1930 and 1936, Way^{5,6} published case reports with histologic descriptions. In 1933, Levin and Tolmach⁷ reported a case in which the main clinical pictures of the skin corresponded typically with the accepted pictures of purpura annularis telangiectodes, and in which an autopsy was performed. Unfortunately, the latter cannot be accepted unreservedly because no histologic study of the skin lesions was made, and the described clinical course and gross autopsy findings were those of bacterial endocarditis, in which event, purpuric lesions might be expected to occur. In 1942, Wise⁸ published a review of the clinical and histopathological features of purpura annularis telangiectodes with its differential diagnosis from progressive pigmentary dermatosis (Schamberg⁹). The following case report seems justified because the clinical and etiologic investigation was more extensive than in any previously reported case.

H. L. J., a 20-year-old unmarried woman, was first seen at the Hitchcock Clinic on March 26, 1942, complaining of skin lesions on the lower halves of the legs. For 5 or 6 months she had had oozing, pustular lesions on both ankles, and for 2 weeks she had noted maculopapular, circinate, symptomless lesions over the lower halves of the legs, accompanied by slight edema of the left ankle. On May 29, she was seen by a dermatological consultant, Dr. Arthur M. Greenwood, of Boston, who made the diagnosis of purpura annularis telangiectodes. She was next seen on July 9, at which time no essential change in the skin lesions was noted.

The parents and seven siblings were living and well, and the family history was not remarkable in any way. In her childhood the patient had had measles, mumps, whooping cough and chicken pox, without complications. There was no history of rheumatic fever or of operations, injuries, major illnesses or previous hospitalizations. She had graduated from high school 2 years previously and had been a telephone operator for 1 year. The menses had begun at the age of 12 and had always been regular.

Physical examination was not remarkable, except for the skin lesions. The cardiac impulse was detected 8 cm. to the left of the midline in the 5th intercostal space. The sounds and rhythm were normal. The height was 66 inches and the weight 143 pounds. The temperature was 98.6°F., the pulse 80, and the blood pressure 110/60. There were purpuric, circinate, ulcerating, scarring, pigmented lesions of the legs and ankles and slight edema of the left foot. Two blood Hinton and two blood Kahn tests were negative. The red-cell count was 4,350,000 and the hemoglobin 11.8 gm. (Klett method). The white-cell count was 5350, with 2 per cent eosinophils, 1 per cent stab neutrophils, 60 per cent segmented neutrophils, 32 per cent lymphocytes and 5 per cent monocytes. The hematocrit was 40 per cent. The sedimentation rate was 74 mm. in one hour, and at another time 55 mm. The bleeding time was 2 minutes and 40 seconds, and the clotting time was 3 minutes. The platelet count was 217,500. The prothrombin time was 32 seconds (normal, 30 seconds). The blood nonprotein nitrogen was 25 mg., the blood sugar 83 mg., the plasma chlorides 590 mg., the serum cholesterol

*From the Medical Service of the Hitchcock Clinic and the Pathological Laboratory of the Mary Hitchcock Memorial Hospital, Hanover, New Hampshire.

†Member, Hitchcock Clinic, member, staff of the Mary Hitchcock Memorial Hospital, instructor in medicine, Dartmouth Medical School.
‡Formerly, assistant, Pathological Laboratory, Mary Hitchcock Memorial Hospital and Dartmouth Medical School.

102 mg., the serum calcium 9.3 mg., and the serum phosphorus 3.3 mg. per 100 cc. Agglutination tests with *Brucella* organisms were negative. The plasma ascorbic acid was 1.5 mg. per 100 cc. A second-strength, intradermal tuberculin (P. P. D.) test was negative. A tourniquet test was negative. A radiograph of the veins of the left leg was performed after the injection of Diodrast into a superficial vein on the dorsum of the left foot. This showed normal visualization of the draining veins up to the femoral and external iliac veins. A radiograph of the chest was normal. An electrocardiogram was normal.

A biopsy of skin of the left leg was performed, the specimen being taken from an area showing telangiectasia, hemorrhage, pigmentation and atrophy. At the time of the biopsy, aerobic and anaerobic cultures were taken from the subcutaneous tissue, and these were sterile. Cultures on Sabouraud's medium were also sterile. Portions of the tissue were fixed in 10 per cent formalin and in Zenker's and Bouin's fluids, and the following stains were made: hematoxylin and eosin, Weigert's elastic tissue, Ziehl-Neelsen's, Masson's trichrome, and Turnbull-blue stain for iron. Serial sections were studied. A few capillaries showed hyaline thickening without other changes; others showed hyalinization of the walls accompanied by the formation of hyaline thrombi that completely occluded the lumens. There were scattered red cells in the connective tissue around such vessels, and an occasional widely dilated capillary with a ruptured wall was seen. In other areas there were proliferative intimal thickenings nearly occluding the lumens and, occasional round areas were seen that appeared to be recanalized, previously thrombosed vessels. These were surrounded by small collections of lymphocytes with occasional plasma cells and eosinophils. The capillaries around the hair follicles and sweat glands were particularly involved. Most of the other capillaries involved were in the superficial layers of the dermis. In some sections there was marked atrophy of the epidermis, which consisted of only two or three layers of cells; the immediate underlying dermis was fibrotic and showed hyalinized and thrombosed capillaries with extravasated red cells. Many of the sweat glands showed atrophic and fibrotic changes. In some of the hemorrhagic areas there were small collections of brown, granular pigment around the blood vessels, and these took the iron stain. The small arteries and veins of the subcutaneous tissue adjacent to the dermis were free of thrombotic and inflammatory changes. The elastic-tissue stain showed an apparent decrease in the elastic fibers of the dermis.

No acid-fast bacilli were found in the sections stained by the Ziehl-Neelsen method. (The perinuclear vacuolization of the epidermis described by Way⁵ appears to have no significance, since it has been seen in numerous sections of stratified squamous epithelium, including apparently normal tissues.)

SUMMARY

A case of purpura annularis telangiectodes is reported.

Extensive laboratory tests gave essentially normal values with the following exceptions: the blood cholesterol was moderately low, and the sedimentation rate was markedly elevated.

Histologic study of the skin lesions revealed thromboses, inflammatory changes in and around small blood vessels, hemosiderin deposits and atrophy, all of which have been previously described.

This case furnishes no evidence that purpura annularis telangiectodes is a dermatologic manifestation of a cardiovascular disease.

ADDITION. In the paper "Pathology, Clinical Manifestations and Treatment of Lesions of the Intervertebral Disks" by Dr. Albert Oppenheimer, which appeared in the January 27 issue of the *Journal*, the following sentence should have been added to the first footnote in column 1, "Awarded the first prize in the competition for the Pray and Burnham Awards offered by the Trustees of the New Hampshire Medical Society."

MEDICAL PROGRESS

BLOOD BANKS AND BLOOD TRANSFUSION (Concluded)*

JOSEPH F. ROSS, M.D.†

BOSTON

TRAUMATIC SHOCK, BURNS AND HYPOPROTEINEMIA

The importance of the plasma proteins in the treatment of shock, burns and hypoproteinemia has been reviewed recently by Janeway⁶⁴ in this series of articles, and will not be repeated here. It may be pointed out, however, that desiccated plasma and solutions of albumin were developed specifically for use by the armed services, and their greatest value lies in their stability at room temperature for prolonged periods of time and in their concentrated form, which allows shipment in a minimum amount of space. For civilian use it is more convenient and economical to preserve whole plasma in the frozen state, and such plasma is probably more suited for general use than are the desiccated or fractionated products. Liquid plasma stored at 4°C. or at room temperature maintains its effectiveness in restoring the osmotic pressure of the blood,⁶⁵ but loses several of its other properties and is therefore not so satisfactory as is the frozen product.

In the event that plasma is not available, transfusion of whole blood should not be withheld from burned or shocked patients merely because hemoconcentration exists. In such cases donor blood is relatively dilute in comparison with the recipient's blood, and transfusion tends to arrest the development of further hemoconcentration.⁶⁶

Transfusion of whole blood is indicated in patients in shock when hemorrhage has been severe, and in burned patients when hemolytic processes⁶⁷ or inhibition of bone-marrow function has led to a lowering of the hematocrit.⁶⁸

INFECTIONS AND INFECTIOUS DISEASE

Specific and nonspecific antibacterial and antitoxic substances may be transferred by transfusions of fresh blood or plasma and are frequently of considerable value in the treatment of infections and infectious diseases.⁶⁹ Attempts to increase the concentration of these immune substances in the transfused material have led to the use of convalescent serums, immunotransfusions and highly concentrated immune globulins prepared from convalescent human subjects or immunized animals. Convalescent serums and immune globulins have proved highly successful in the treatment of certain infections — for example, scarlet fever, measles, mumps and pneumococcal and influenzal infections.⁷⁰ Im-

munotransfusion has not been so generally successful, probably because of the fact that the concentration of antibodies developed in the donor as a result of vaccine injections are not so high as those already present in the recipient.⁷¹ Lyons,⁷¹ however, reported that transfusions of blood from properly selected donors were of considerable value in the treatment of hemolytic streptococcus infections.

The role of transfused leukocytes in combating infection has not been established. Donor leukocytes may aid in combating disease,⁶⁹ although it is not possible to elevate significantly the recipient's white-cell count by transfusion. Transfusion is of little or no value in the treatment of agranulocytic angina.⁷² It is frequently indicated in acute and chronic infections to supply erythrocytes and plasma protein. Occasionally, the benefits derived from such supportive therapy are pronounced.

Although the immune globulin substances appear to be quite stable, complement, leukocytes and perhaps other important antibacterial substances rapidly degenerate in stored blood.^{44, 55, 69} Consequently, fresh blood should be used for maximum effectiveness in the treatment of infections.

PRECAUTIONS

The importance of establishing absolutely the compatibility of blood before transfusion cannot be overemphasized. An error in blood grouping or cross-matching may — and all too frequently does — result in a severe transfusion reaction and death. Tests of compatibility should be performed only by adequately trained persons, and the materials and technics used must be scrupulously controlled. Excellent and concise descriptions of blood-grouping technics, with practical considerations of necessary precautions and sources of error, are to be found in the manual by Schiff and Boyd⁷³ on blood-grouping technic, which should be readily available in every laboratory performing such tests.

In contrast to the universally employed procedure of establishing donor-recipient compatibility in respect to the A, B, AB and O groups, tests for the Rh factor are not widely used, and until recently were performed only in a few research laboratories. The importance of the Rh factor as an isoantigen has recently been discussed by Hooker⁷⁴ and Wiener,⁷⁵ and it is apparent that most intragroup hemolytic transfusion reactions are caused by transfusion of Rh+ blood into sensitized Rh- recipients.⁷⁶ Even though the Rh factor is a poor antigen, and only 15 per cent of the white population is Rh-, the hazards associated with transfusion of Rh-incompatible blood

*From the Robert Dawson Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine. Prepared under tenure of a Welch Fellowship in Internal Medicine of the National Research Council.

†Associate Professor of Medicine, Massachusetts General Hospital, Boston.

are so great that tests for the Rh factor and transfusion of Rh-compatible blood should be made a routine procedure for all transfusions. Certainly, transfusions should never be given to pregnant women or to recipients receiving repeated transfusions unless Rh compatibility has been established.

Unfortunately, *in vitro* cross-matching tests — even with Landsteiner's test-tube technic and with incubation and chilling of the serum-cell mixtures — do not always detect potentially sensitive Rh-recipients. The avoidance of Rh-incompatible reactions can be ensured only by making tests for the Rh factor in the cells of both donor and recipient, and by transfusing Rh- recipients with Rh-blood. Such determinations require the use of potent Rh-agglutinating serum, which is still difficult to procure. Rh-factor determinations, however, can usually be obtained in centrally located laboratories.*

The indiscriminate use of so-called "universal donors" is dangerous, since transfusion of Group O blood may produce severe hemolytic reactions.⁷⁷ Hesse⁷⁸ reports that, in 46 cases, transfusion of universal-donor blood caused 20 deaths. He recommends that universal-donor blood be used only in cases of extreme emergency, and then only if the agglutinating titer of the donor serum for the recipient's cells is not higher than 1:32. Neutralization of isoagglutinins with specific Group A and Group B antigens has been recommended by Witebsky, Klendshoj and Swanson⁷⁹ and appears to make even high-titer Group O blood safe for transfusion into members of other blood groups. The pooling of several lots of plasma so dilutes and neutralizes the isoagglutinins contained in any one plasma that pooled plasma may be given without the hazard of producing intravascular agglutination.⁸⁰

The rate at which blood may be transfused safely depends to a large extent on the functional integrity of the recipient's cardiovascular system. In normal persons as much as 650 cc. of blood has been given in three minutes without adverse reaction⁸¹; the rate of flow usually recommended is 40 to 60 drops per minute, or 250 cc. per hour.

Blood and plasma that have been refrigerated may be transfused safely without preliminary warming.⁸² Indeed, mistaken attempts at warming may actually produce hemolysis or protein denaturation. Frozen plasma should be thawed at a temperature of 37°C., and the time used for thawing should not exceed thirty minutes. Slower thawing or thawing at room temperature results in the formation of a heavy fibrin precipitate.

Stored blood or plasma should be filtered before being transfused, since small aggregates of fibrin are prone to develop in even the best preservatives, and the introduction of such thrombi into the venous system may produce a fatal reaction.⁸³ Most filters tend to become clogged with these fibrin aggregates,

*In the New England area, Rh-factor determinations and potent Rh-agglutinating serum may be obtained from the Blood Grouping Laboratory (Children's Hospital, 300 Longwood Avenue, Boston).

with the result that they are frequently discarded and the blood or plasma is given without filtration. This is highly dangerous, since if there is enough precipitate to clog a filter, it will certainly clog the arterioles or capillaries somewhere in the recipient's body. Although not ideal, the glass-bead filter recommended by the British Medical Research Council^{84, 85} has proved satisfactory at the Massachusetts Memorial Hospitals.

Every precaution must be taken to prevent the transmission of disease by transfusion. The mere performance of a serologic test for syphilis is not adequate, since highly infectious syphilis may exist before the reaction becomes positive and even before the primary lesion appears.⁸⁶⁻⁸⁸ Eichenlaub and Stolar⁸⁹ state that in 41 cases of transfusion syphilis serologic examinations would not have aided in detecting the disease in 18 of the infected donors. Serologic testing of donors must be complemented by careful physical examination and questioning to exclude the possibility of latent or seronegative syphilis.

In view of the long latency of malaria, it may be unwise to use persons with a past history of this disease as blood donors, even though examination of a blood smear fails to reveal the presence of parasites.

The epidemic of jaundice following yellow-fever inoculations in the United States Army has been traced to the presence of small amounts of pooled human serum in the vaccine,⁹⁰ and it appears that the jaundice-producing agent is a filterable virus.⁹¹ Similar attacks of jaundice have been produced by the transfusion of blood and of convalescent serum,^{92, 93} and are presumably caused by a similar agent. The implications of these findings in the selection of blood donors are not yet definite, since donors of some of the jaundice-producing bloods are apparently healthy and there is no way of determining that their blood is icterogenic.

TRANSFUSION REACTIONS

Hemolytic transfusion reactions are unfortunately much more frequent than is usually suspected, the average incidence being about .2 per 1000 transfusions, with a mortality of 1.4 deaths per 1000 transfusions.⁹⁴ These rates place the risk of blood transfusion in the same range as the risk of some major operations, a fact that is all too often neglected. Many physicians take elaborate precautions to safeguard against much less important hazards, but depend on a young intern or an inadequately trained technician to establish the compatibility of donor blood. Fortunately, transfusion of incompatible blood does not always result in serious complications,⁹⁵ but the usual course of events following such transfusions is intravascular agglutination and hemolysis, hemoglobinemia, hemoglobinuria, severe systemic symptoms, oliguria, anuria, uremia and death in at least half the cases.^{78, 94, 96}

The pathogenesis of the renal failure that is the usual cause of death in these accidents is still ob-

sure. Considerable doubt has been cast on the theory that anuria and uremia are produced by mechanical blockage of the renal tubules by hemoglobin casts precipitated in acid urine, and on the belief that such blockage can be prevented by keeping the urine alkaline.⁹⁷⁻⁹⁸ Careful studies of kidneys from cases of fatal transfusion reactions have failed to account for the anuria on the basis of renal tubular obstruction. The primary lesion in such kidneys is a marked degenerative change in the convoluted and collecting tubules.^{17, 99} Furthermore, large amounts of pure hemoglobin may be injected intravenously and excreted in acid urines without producing any decrease in renal function or any untoward reaction.^{99, 100} Finally, maintenance of an alkaline urine in several typical hemolytic transfusion reactions did not prevent death.⁹⁹

It appears probable that transfusion-reaction nephritis is produced by the action of some toxic or antigenic substance on the tubular epithelium rather than by mechanical blockage of the tubular lumens. The nature of this hypothetical toxin is suggested by the recent experiments of Bing,¹⁰⁰ who found that hemoglobin, methemoglobin and metmyoglobin could be excreted in either acid or alkaline urine without disturbance of renal function so long as the alkali reserve of the subject was normal. Production of acidosis by the intravenous injection of lactic acid or hydrochloric acid prior to the injection of methemoglobin produced typical transfusion-reaction nephritis, with anuria, uremia and death. Such findings suggest that fatal human reactions occur when methemoglobinuria develops in patients with markedly reduced alkali reserves, as in severe shock.

The extreme seriousness of hemolytic transfusion reactions and the fact that about half the patients developing anuria die make it absolutely essential that effective therapeutic measures be instituted immediately in any patient suspected of having such a reaction. In spite of the evidence that transfusion-reaction nephritis is not produced by mechanical blockage of renal tubules, abundant clinical and experimental evidence supports the practice of alkalinizing the urine in all suspected cases.^{96, 101} To be effective, alkalinization must be accomplished rapidly, and this usually necessitates parenteral administration of alkalinizing agents. Because of the ready availability of sodium citrate in sterile ampoules in hospitals where transfusions are given, several authors have recommended the slow intravenous injection of 100 to 200 cc. of a 2.5 or 3.0 per cent solution of the drug, which, it is stated, produces a neutral or alkaline urine within fifteen minutes.^{102, 103} More physiologic in action, safer and probably more effective in alkalinizing the urine are solutions of sodium lactate ($\frac{1}{2}$ molar) and sodium bicarbonate (4 to 6 per cent), which can be procured in sterile ampoules and which should be available for immediate use in any hospital where trans-

fusions are administered. The oral administration of adequate amounts of sodium bicarbonate or other alkalis¹⁰² produces an alkaline urine, but the length of time and the amounts required vary greatly in different persons. Numerous other therapeutic measures directed toward stimulating renal function and the secretion of urine have been advocated, but there is little evidence of their effectiveness.¹⁰⁴ Transfusion of fresh compatible blood as soon as possible after the hemolytic reaction has occurred does appear to be of some value, perhaps because of its effect in stimulating blood flow through the kidneys.¹⁰⁵

It is evident from the confusion concerning the pathogenesis of transfusion nephritis and from the nonspecific nature and frequent failures of the numerous recommended therapeutic measures that the treatment of hemolytic transfusion reactions is unsatisfactory. It is better to avoid the necessity for such treatment by ensuring the compatibility of donor blood than it is to attempt treatment once a reaction has occurred.

Febrile reactions to transfusion are fairly frequent, and as a rule can be explained by the presence of pyrogens or impurities in solutions or by improperly cleaned glassware or tubing. Such febrile reactions may be serious in recipients who are critically ill or extremely anemic, and must be carefully guarded against by observing a scrupulous technic.

Allergic and anaphylactic reactions occur in 1 or 2 per cent of transfusions.⁹⁵ They vary in severity from mild urticaria to severe anaphylactic shock. Usually such reactions are mild and can be controlled by the injection of 5 to 10 minims of a 1:1000 solution of adrenalin. This type of reaction can be decreased in frequency by using only fasting donors, and it is now a routine requirement in many blood banks that donors must abstain from food for four to six hours before venesection is performed.

* * *

Blood banks and improved methods for the preservation of erythrocytes have made transfusion of whole blood a simple, economical procedure and have extended tremendously the therapeutic usefulness of transfusions. Blood plasma, originally a byproduct of the blood bank, now has its own particular fields of usefulness, and can be stored almost indefinitely without loss of therapeutic efficacy. The next great advance in transfusion therapy will no doubt be the preparation and use of purified fractions of the plasma proteins, — albumin (already in use), fibrinogen, thrombin, complement, specific immune globulins, isoagglutinins, enzymes and hormones, — each filling a particular therapeutic need.

EDITH E. PARRIS, *Assistant Editor*

CASE 30071

PRESENTATION OF CASE

A forty-one-year-old housewife entered the hospital because of diarrhea.

The patient was in apparent good health until three and a half years before entry, when she developed numerous grossly bloody stools accompanied by crampy, low abdominal pain. Three years before admission she had an x-ray examination and was told that she had a "duodenal ulcer." On a Sippy diet and "injections" she had considerable relief for a period of two years. It is not known what the injections consisted of and whether there was an examination of the stools. Six months before admission she developed vague, distressing, abdominal discomfort just below the left costal margin. The pain was not severe and had no relation to meals. Four months before entry she had sudden, severe, prostrating, left subcostal pain and stayed in bed for seven weeks. Following this she was extremely weak; she was able to get up but stayed at home. She had intermittent attacks of subcostal, flank and lower costal pain on the left. About two weeks before admission she developed loose liquid stools alternating with normal stools. There was no blood, tarry material or recognizable food particles in the stools. On one occasion at that time she vomited foul-smelling material. She was taken to a community hospital where barium studies were performed. She had lost 50 pounds in four months. No additional information was available except that she had had a hysterectomy and appendectomy three years before entry.

Physical examination showed a well-developed, poorly nourished pale woman. There was a slight apical systolic murmur, but the heart and the lungs were not otherwise remarkable. The liver was palpable at the costal margin. In the left upper quadrant was a palpable, tender mass from which a tubular structure extended to the right upper quadrant. There was tenderness in the left subscapular region.

The blood pressure was 116 systolic, 68 diastolic. The temperature was 98.6°F., the pulse 75, and the respirations 20.

*On leave of absence

Examination of the blood showed a white-cell count of 14,000, with 87 per cent neutrophils. The hemoglobin was 8.5 gm. per 100 cc. The blood protein was 4.4 gm. per 100 cc. The urine gave a + test for albumin. A gastric analysis showed free hydrochloric acid and was guaiac negative. The stools were guaiac positive. A blood Hinton test was negative.

A gastrointestinal series showed a rather large stomach. A wide fistulous tract, measuring 7 by 1.5 cm., led from the greater curvature of the stomach opposite the cardia to the splenic flexure of the colon (Fig. 1). Peristalsis of the stomach was active, and there was normal passage of barium

FIGURE 1. Roentgenogram following a Barium Meal.

through the pylorus filling a symmetrically non-tender duodenal cap. Six-hour films showed a small amount of barium still in the stomach, mixed with food material. The barium was scattered throughout the small bowel, but little seemed to have passed through the fistulous tract to the left colon. The colon was outlined with barium from rectum to cecum. The barium was mixed with fecal material, apparently following barium examination of the colon before admission.

On the tenth hospital day an exploratory laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: Before reading the x-ray report it is well to pause and see what one can make out of this history. First of all, it seems to me that

we are dealing with a woman who was in poor condition. For instance, she had a hemoglobin of 8.5 gm., which is half what it ought to be. She had a low serum protein, 4.4 gm. per 100 cc., whereas it ought to be in the neighborhood of 6 gm. She had a + test for albumin in the urine. These findings, I think, indicate that the woman was seriously ill, and had a condition that had probably been going on for some time. The first indication of anything wrong was three and a half years before she was admitted, and at that time she apparently passed grossly bloody stools accompanied by crampy, lower abdominal pain.

The passage of blood in the stools may be due to several things. First of all it may be due to hemorrhoids. If it was due to hemorrhoids, one would not expect it to be associated with lower abdominal pain. One should never stop at that diagnosis without investigating the colon further, both by sigmoidoscopy and barium enema, which was not done. Occasionally one sees grossly bloody stools from a duodenal ulcer. She did have a gastrointestinal series at that time, and a diagnosis of a duodenal ulcer was made. Whether she had that or not, I am not certain, but I am sure that that is not what she was suffering from when she came into the hospital.

The next thing of interest in the history is that six months before admission she developed vague, distressing, abdominal discomfort below the left costal margin. We have for the first time some evidence of the localization of the lesion. Four months before entry she had sudden, severe, prostrating, costal pain on the left, and later there was a mass noted in the left costal region. What conditions can give symptoms in this region with a presumable mass? The first one is pancreatitis, in view of the fact that some extension of the mass toward the right upper quadrant was noted, which is the general distribution of the pancreas. It seems to me that a patient with severe left subcostal pain could very well have a pancreatic lesion, not a hemorrhagic pancreatitis but some form of pancreatic cyst or low-grade pancreatitis. Again she may have had a lesion in the stomach, as the stomach lies in the left upper quadrant. It may have been a carcinoma of the stomach, with a subacute perforation into the left upper quadrant that had sealed off. Another condition is a lesion in the splenic flexure of the colon, such as diverticulitis or carcinoma. One cannot forget also that the kidney and the spleen are in the left upper quadrant, but we have no evidence that either of these organs was involved. Furthermore, in the laboratory studies it is important to notice that the patient showed free hydrochloric acid in the gastric analysis. There was no blood in the gastric analysis, but the stool did give a positive guaiac test. From that I conclude that she was not suffering from carcinoma of the stomach and that the blood in the stools was more likely coming from a lesion in the colon rather than from one in the stomach.

I am a little confused about the x-ray report. Perhaps it is correct as written, but I should like to ask Dr. Robbins whether the barium went from the stomach into the splenic flexure. Apparently it did not go from the splenic flexure into the stomach.

DR. ROBBINS: This is the point at which the barium, as I understand it, was said to go through from the stomach to the splenic flexure. I think there is definite evidence of rigidity of the wall of the stomach. This is the fistulous tract, and in this projection it shows best on the spot films. It is distorted and fairly long. There is a narrowed area in the distal transverse colon at the point where the fistula enters.

DR. LINTON: It is obvious from the x-ray films that she had a gastrocolic fistula, and I think that one can pick out several confirmatory items in the history. For instance, it is stated that two weeks before entry she developed liquid stools alternating with normal stools. That does not necessarily mean that she had a gastrocolic fistula but suggests it. On one occasion there was vomiting with foul-smelling material. These two things ought to make one think of gastrocolic fistula in a patient with a lesion in the upper abdomen. It is perfectly obvious from these x-ray films, which help us in diagnosing the lesion, that the condition was not one of pancreatic or duodenal origin.

I believe that there are three possibilities to be considered: carcinoma of the stomach with perforation and a fistulous tract into the colon; carcinoma of the colon with the reverse taking place; and a benign lesion, such as a diverticulum, that had formed an abscess and had perforated into the stomach. I think the last mentioned is the least likely in view of the fact that the patient showed evidence of chronic disease—the low hemoglobin and low serum protein. It is up to me to decide whether she primarily had carcinoma of the colon or of the stomach, which is a fairly hard decision to make. The fact that there was rigidity in the stomach wall makes me favor a primary lesion in the stomach rather than one in the colon. Furthermore, a lesion that had been going on as many years as this one had, if it involved the colon, would ordinarily have given obstructive signs, which apparently were not present. This lesion was in a silent area in the stomach and could have gone undiagnosed for some time. When she had the first gastrointestinal series, the lesion was probably overlooked, since it was in the fundus.

My final diagnosis is carcinoma of the stomach, with perforation and the formation of a fistulous tract between it and the colon.

DR. ROBBINS: The rigidity in the wall of the stomach could just as well have been produced by extension from a lesion elsewhere or by an inflammatory process. There is a definite narrow area of ulceration in the colon from which the fistula extends

DR. LINTON: Actually it makes little difference whether the lesion was in the stomach or in the colon, because both organs would have to be resected to relieve the patient. It is merely taking a long chance to see if one can guess the right one.

A PHYSICIAN: How do you explain the absence of occult blood in the stool?

DR. LINTON: I must admit that that is more indicative of a lesion in the colon than of one in the stomach. The free hydrochloric acid is also in favor of a colonic lesion rather than one in the stomach, but free acid does occur in carcinoma of the stomach, so one cannot draw any absolute conclusion.

DR. LELAND S. MCKITTRICK: Our reasoning was much like that of Dr. Linton. We were, however, more impressed by the radiologist's report than Dr. Linton was. We thought that the primary lesion was probably in the colon and that it had gone through into the stomach. We did not, however, feel strongly one way or the other.

We did a transverse colostomy and found an adherent mass in the left upper quadrant, which we did not thoroughly explore. We could not tell much about it but obtained the impression that it might be removable. About three weeks later she was re-operated on. During the interval she had seven or eight transfusions, but the hemoglobin at the end of that period was about 8.5 gm., practically what it was when she came into the hospital. At the second operation it was possible to take out the mass. We removed the greater part of the stomach, the spleen, about half the pancreas and the splenic flexure. Except for a thrombophlebitis involving the deep veins of the left leg, she made an uneventful convalescence.

CLINICAL DIAGNOSIS

Gastrocolic fistula.

DR. LINTON'S DIAGNOSIS

Carcinoma of stomach, with gastrocolic fistula.

ANATOMICAL DIAGNOSES

Adenocarcinoma of transverse colon, with extension into stomach.

Gastrocolic fistula.

PATHOLOGICAL DISCUSSION

DR. RONALD C. SNILEN: As Dr. McKittrick has indicated, the resection included the greater portion of the stomach, the transverse colon, the spleen and a segment of the pancreas. The transverse colon and the stomach were intimately bound together. When the former was opened, an annular tumor about 4 cm. in length was found that had replaced the mucosa. Superiorly, in the center of the tumor, a fistula about 2 cm. in diameter led into the stomach on the greater curvature. From the gastric aspect the fistula was found to be situated in the center of

a mound produced by tumor infiltration of the stomach wall. The mucosa over this mound was ironed out but not destroyed, except at the portal of the fistula. To determine the origin of this tumor one must rely, in part, on the interpretation of the gross findings, and we believe that it arose in the transverse colon. Microscopically it proved to be a fairly well differentiated adenocarcinoma. The spleen was not involved, nor was the pancreas, although both organs were adherent to the mass.

CASE 30072

PRESENTATION OF CASE

A sixty-three-year-old woman was admitted to the hospital because of pain in the left leg.

The patient was in the hospital two years prior to admission because of a pathologic fracture through a benign giant-cell tumor of the left femur. The tumor was excised, leaving only the anterior medial and posterior walls of the cortex, which contained some of the original tumor. Grafts from the ilium were inserted. The patient was asymptomatic and moved around freely until two days before entry when she tripped over a rug and strained her leg, which necessitated the use of a cane. One month before admission she noted a mass in the left lower quadrant of the abdomen. There was no pain except for a "kink" on one occasion. She had no other symptoms.

She had been constipated for many years and had noted no change recently. Seven months prior to admission she noted a small amount of blood in the stools, but none since. A barium enema at that time was negative.

Physical examination showed a grapefruit-sized movable nontender mass in the left abdomen. It could not be moved into the pelvis or the flanks. There was anterior bowing and marked thickening of the left femur.

The blood pressure was 155 systolic, 75 diastolic. The temperature, pulse, and respirations were normal.

X-ray examination of the left femur showed progressive expansion in the involved area since the last examination. This was more marked in the lower portion, where numerous cyst-like cavities were seen that were divided by coarse trabeculae of bone. The bone grafts previously described were still in position and maintained their density. There was evidence of a fairly recent fracture of the anterior cortex at the upper extremity of the involved portion of the femur with anterior bowing, which was greater in degree than it was two years previously. There was no apparent soft-tissue mass in the left pelvis. A barium enema passed without delay from the rectum to the cecum. The proximal sigmoid was displaced laterally by a palpable mass

in the left side of the pelvis. The mass was extrinsic to the sigmoid and not grossly adherent to it. The rest of the colon was negative. A post-evacuation film showed contraction of the entire colon, with normal mucosal relief.

On the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD B. BENEDICT: The first question that occurs to me is a rhetorical one. I might ask why an endoscopist was asked to discuss a bone tumor. The first answer is a flattering one — possibly they thought that I am a good diagnostician. The second is that they wanted to "take me for a ride"; the third, that they could not get anyone else.

DR. RONALD C. SNIFFEN: Let us assume that the first is correct.

DR. BENEDICT: Could the pathologist be mistaken about the pathological diagnosis of benign tumor? You do not have to answer that now, Dr. Sniffen, but you might think about it.

Perhaps we might first look at the x-ray films.

DR. LAURENCE L. ROBBINS: This is the bone lesion as it was originally seen. These films were taken in 1941. The location of the lesion is of interest. Apparently it is a trabeculated lesion with large cystic areas and appears to involve the entire bone, both the cortical and medullary portions. So far as I can see there is no evidence of break in the cortex other than what perhaps can be explained by a small fracture. I see no evidence of a soft-tissue mass. On this film, approximately three years post-operatively, you can see the changes that have taken place. The lesion has continued to expand, with loss of cortex in this area, but that does not necessarily mean that the lesion has become malignant. One wonders about it, however. There is soft-tissue swelling beyond a break in the cortex and evidence of fracture in the upper portion of the lesion, which probably explains the acute episode.

So far as the examination of the colon is concerned, the fluoroscopist definitely had the advantage, but I am inclined to think that the pressure is more on the transverse colon than on the sigmoid; that is, the transverse colon appears to be displaced in the distal portion. The sigmoid may have been displaced fluoroscopically.

DR. BENEDICT: The record states that it was displaced laterally by a palpable mass in the left side of the pelvis.

DR. ROBBINS: If there was a mass I should put it above the transverse colon.

DR. BENEDICT: Was there a chest plate?

DR. ROBBINS: Yes; it was negative.

DR. BENEDICT: There are several things against a benign giant-cell tumor. Geschickter* states that no giant-cell tumor has recurred after primary radi-

cal resection. Furthermore, giant-cell tumors usually occur in the end of the bone. Fractures undoubtedly occur, but I wonder if one could expect two fractures in a recurrent giant-cell tumor. Such tumors occasionally become malignant, and I suppose that could have happened here.

What do you say, Dr. Sniffen, about the possibility of an erroneous microscopic diagnosis?

DR. SNIFFEN: In this case I should say "No."

DR. BENEDICT: Definitely?

DR. SNIFFEN: Yes.

DR. BENEDICT: By microscopic examination?

DR. SNIFFEN: Yes.

DR. BENEDICT: What do you think, Dr. Robbins? Is the bone tumor malignant by x-ray?

DR. ROBBINS: The sections were taken at the time of the original films, and we do know that some giant-cell tumors become malignant. I do not know whether this is malignant now.

DR. BENEDICT: I should like to relate the lesion to the abdominal mass, carrying out Dr. Richa Cabot's teaching of having one diagnosis to cover everything. In that case it would have to be malignant tumor in the abdomen with metastases to bone. I thought of an ovarian tumor, but it was described as not being in the pelvis, and ovarian tumors seldom metastasize to bone. Furthermore, the plain film of the pelvis was said to have been negative. Tumors of the colon do go to bone, but not often. The barium enema was negative except for an extrinsic mass, which tends to rule out the colon.

The tumors that metastasize to bone common are those that originate in the prostate, breast, thyroid gland and kidney. I suppose that examination of the breast and thyroid gland was done and that a mass would have been noted. Tumors of the kidney frequently metastasize to bone, and the mass felt in the abdomen is consistent with a renal tumor. In addition, symptoms of the metastatic lesion rather than of the primary tumor may appear first. There is no record of x-ray films of the kidneys. The urine is not reported, and there was no pyelogram. Is there anything in the record about these?

DR. SNIFFEN: The only finding recorded of remote significance is a rare red cell and rare white cell in the urine.

DR. ROBBINS: I think that I can see the left kidney; it appears to be normal.

DR. BENEDICT: Tumors of the lung and occasionally those of the stomach and esophagus go to bone, but we have no evidence of anything in the chest, stomach or esophagus. Lymphoma occasionally goes to bone, but usually to the vertebrae and this is not the x-ray picture of a lymphoma. Pathologic fractures are uncommon in lymphoma of the bone, and there should have been other evidences of lymphoma. From the x-ray standpoint this is apparently not an osteogenic sarcoma, because there is new-bone formation at the epiphyses

*Geschickter, C. F., and Copeland, M. M. *Tumors of Bone*. 709 pp. Philadelphia: Lancaster Press, 1931. P. 325.

end. Furthermore, the patient is usually somewhat younger and pathologic fractures frequently occur. I was going to put all my money on a hypernephroma with metastases to the femur, but Dr. Robbins and Dr. Sniffen believe that this is not a malignant bone tumor, and Dr. Robbins says that the left kidney outline is normal so far as he can tell. I do not know of any way to explain these two conditions on the basis of a benign giant-cell tumor except by making two diagnoses, and even then I cannot name a tumor of the left lower quadrant that is not in the pelvis, not in the flank and not in the colon. In spite of all the arguments against a malignant bone tumor I am going to say that this was a hypernephroma with metastasis to the femur.

DR. BENEDICT'S DIAGNOSIS

Hypernephroma, with metastasis to femur.

ANATOMICAL DIAGNOSIS

Malignant lymphoma, lymphoblastic type, of stomach, with extension to transverse colon and involvement of regional lymph nodes.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: Dr. A. W. Allen operated on this patient, and I am sorry he is not here to discuss the case. I shall read a portion of his operative findings.

The abdominal mass just below and to the left of the umbilicus was found to be a massive cancer in the region of the midtransverse colon. There were implants in the

FIGURE 1. Photograph of Stomach.

DR. FLETCHER H. COLBY: Would you expect a renal tumor to displace the colon the way this did?

DR. ROBBINS: No; but I cannot be sure about the displacement of the colon. The fluoroscopist said one thing, but what I see on the films is transverse colon that may be displaced by a renal tumor. There is one peculiar thing — the gas shadow above the transverse colon appears to be in the mass displacing the colon; if one considers both films together, the gas shadow could be due to something in the stomach.

CLINICAL DIAGNOSES

Ovarian cyst.

Carcinoma of stomach.

great omentum and in the gastrocolic ligament. Further exploration revealed that the source of the tumor lay in the stomach itself. There were nodes along the left gastric vessels, and nodes posteriorly to the celiac axis. The liver, however, was entirely free of disease; moreover there were no free peritoneal implants. After evaluation of the entire situation we decided that the tumor was resectable.

A total gastrectomy, a transverse colectomy and a splenectomy were performed.

I do not see how Dr. Benedict could possibly have made the diagnosis. I am afraid that he was the victim to illustrate an interesting gastric lesion. The two lesions were not related; the bone lesion was a benign giant-cell tumor.

The resected specimen was one of stomach, transverse colon and spleen. In the stomach there were two major masses, one on the greater curvature,

about 10 cm. in diameter, and the other on the lesser curvature, about 7 cm. in diameter (Fig. 1). These were separated by several centimeters. In the rest of the mucosa there were several smaller nodules, and the rugae in general were large and moderately firm. Both masses invaded all coats of the stomach and had reached the serosa. The larger mass had invaded the transverse colon, which contained a small submucosal nodule. The mucosa over the tumors was atrophic, but apart from an area of central ulceration over the larger mass, it was intact. These lesions microscopically proved to be lymphoma of the lymphoblastic type.

It might be well to stress the fact that when one finds this picture — multiple tumors that originate in the stomach wall, protrude into the lumen and iron out the mucosa, with a central area of ulceration — one should seriously entertain the diagnosis of lymphoma. This also holds for the connective tissue tumors, such as leiomyosarcoma and fibrosarcoma. Some of the regional lymph nodes were free from lymphomatous change, and some were involved. In an early lymphoma of the stomach one does not expect the lymph nodes to be involved, but in an advanced tumor such as this, it is more likely. The spleen was normal.

REHABILITATION AND RE-EMPLOYMENT

THE number of men rejected by the armed forces or honorably discharged with a "certificate of disability" is already great and will, of necessity, increase to an extent that may make it a difficult task for the civil community to absorb them adequately and gainfully. The proper rehabilitation and re-employment of these men is of the utmost importance if we are to avoid the tragic aftermath of the last war, and much of the responsibility for any future program rests on the civilian physician — for to him the discharged soldier will and should turn for help, guidance and assurance.

It is well to remember that the primary if not the sole objective of the induction stations of the armed

forces is to procure a sufficient number of men who are physically fit for the rigors of general military service. The rejection of a selectee does not imply that he is incapable of living a normal existence or of being a useful civilian in his community, as he may well have been in the past. In a similar way, men are discharged from the armed forces with a "certificate of disability" because, for one reason or another, they are no longer able to stand the extreme stress and strain of modern warfare. Again there is no necessary implication that these men cannot return to a useful civilian life; they have been discharged solely because they are not fit for combat duty. It has not, however, been sufficiently stressed or publicized that many men are rejected or discharged for defects entirely compatible with normal civilian life. The man who has been rejected by an induction station or discharged from the armed forces may have a previously undiscovered disease that can and should be treated by his own physician. On the other hand, it must be emphasized that chronic diseases, either mental or physical, that have previously been known should gain no new significance or importance when the soldier returns to his home. The mere fact that he has been rejected or discharged must neither be a stigma against the man nor a cause of special anxiety to his family and friends, though all too frequently it is. The high-strung, tense person with frequent gastric complaints without organic basis presents no new problem when he returns home with the diagnosis "psychoneurosis, anxiety type." If he was an acceptable and useful member of society before, there is no reason why he should not continue to be such, provided his problem is understood and he himself is helped.

A man may have been gainfully employed for a period of years and yet be rejected by the armed forces for some psychiatric trait that makes him inefficient as a soldier; this fact renders him no less efficient as a civilian employee. Personality disorders that might well disqualify a man or cause his subsequent discharge again acquire no new significance. What may upset the family and may prejudice a future employer is that traits which had in civil life been regarded as erratic conduct or personal peculiarities were considered by the medical officers to be disqualifying for combat service. A man may be rejected for "healed tuberculosis," yet this diagnosis may thoughtlessly be translated into

about 10 cm. in diameter, and the other on the lesser curvature, about 7 cm. in diameter (Fig. 1). These were separated by several centimeters. In the rest of the mucosa there were several smaller nodules, and the rugae in general were large and moderately firm. Both masses invaded all coats of the stomach and had reached the serosa. The larger mass had invaded the transverse colon, which contained a small submucosal nodule. The mucosa over the tumors was atrophic, but apart from an area of central ulceration over the larger mass, it was intact. These lesions microscopically proved to be lymphoma of the lymphoblastic type.

It might be well to stress the fact that when one finds this picture — multiple tumors that originate in the stomach wall, protrude into the lumen and iron out the mucosa, with a central area of ulceration — one should seriously entertain the diagnosis of lymphoma. This also holds for the connective-tissue tumors, such as leiomyosarcoma and fibrosarcoma. Some of the regional lymph nodes were free from lymphomatous change, and some were involved. In an early lymphoma of the stomach one does not expect the lymph nodes to be involved, but in an advanced tumor such as this, it is more likely. The spleen was normal.

MEDICAL EPONYM

SCHMORL'S DISEASE

Dr. Christian Georg Schmorl (1861-1932), discussed "Ueber Dehnungs- und Zerreißungsvorgänge an den Bandscheiben und ihre Folgen. [Events Preceding Expansion and Rupture in the Menisci and their Results]" at the twenty-second session of the Deutsche Pathologische Gesellschaft in Danzig, June 8 to 10, 1927. A report of his presentation may be found in the *Centralblatt für allgemeine Pathologie und pathologische Anatomie* (40:244-246, 1927). A portion of the translation follows:

The normal turgor of the menisci may thereby so injure the spongiosa of the vertebral bodies as to lead to an abnormally marked indentation of the menisci. This is particularly the case if the spongiosa has deteriorated as the result of disease of the bone substance or the marrow, and its weight-bearing capacity damaged. . . .

Under normal conditions also an injury to the spongiosa may result from the pressure due to turgor. This injury may be especially observed in young persons in whom endochondral growth is in process of conclusion or indeed has ceased. The injury is here limited to the region of the nucleus and is most probably to be attributed to a deterioration of the cartilage plates. . . .

As a result of the indentation of the menisci there takes place an extension and thinning of the cartilage plates. Finally, excessive expansion, characterized by the formation of delicate fissures and rupture, occurs, usually in the nuclear region on both surfaces of one and the same meniscus at symmetrically located points. . . .

. . . cavities of greater or lesser size arise in the spongiosa. . . .

Cartilaginous nodules appear, which frequently lie at symmetrically situated points of the two surfaces of the menisci.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

COUES — William P. Coues, M.D., of Brookline, died January 13. He was in his seventy-second year.

Dr. Coues received his degree from Harvard Medical School in 1894. He was appointed senior intern in surgery at the Massachusetts General Hospital in 1894. He was a member of the Massachusetts Medical Society and the American Medical Association.

CRONIN — Edward J. Cronin, M.D., of Brighton, died February 11. He was in his forty-seventh year.

Dr. Cronin received his degree from Tufts College Medical School in 1921. He interned at St. Elizabeth's Hospital and was staff secretary there at the time of his death. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, five children, three sisters and five brothers survive.

EMERSON — Francis P. Emerson, M.D., formerly of Boston, died at the home of his daughter in Franklin on January 19. He was in his eighty-second year.

Dr. Emerson received his degree from Columbia University College of Physicians and Surgeons in New York, in 1886. He was formerly a member of the New York Eye and Ear Infirmary and the New York Medical College. At one time he was a member of the staffs of the Brooks Hospital and the Massachusetts Women's Hospital. He was a member of the Massachusetts Medical Society, the American Medical Association, the American Association for the Advancement of Science, the American Otological Society, the American Laryngological Society and the New England Laryngological and Otological Society.

One daughter survives.

KITE — Walter C. Kite, M.D., of Milton, died February 5. He was in his eightieth year.

Dr. Kite received his degree from the University of Pennsylvania School of Medicine, Philadelphia, in 1893. He served internships in hospitals in Philadelphia, Atlantic City and Wilkes-Barre, Pennsylvania. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son, a daughter, a grandson and a brother survive.

RICHARDSON — Edward P. Richardson, M.D., of Brookline, died January 26. He was in his sixty-third year.

Dr. Richardson received his degree from Harvard Medical School in 1902 and for sixteen months before graduating was surgical house officer at the Massachusetts General Hospital. As a specialist in surgery he was at various times, assistant visiting surgeon to the Massachusetts General Hospital, and consulting surgeon to hospitals in Gardner, Milford, Brockton, Attleboro and Plymouth. In 1915, he served with the First Harvard Medical Unit at British General Hospital No. 22, near Etaples, France, as a temporary honorary major. In July, 1918, he was commissioned a captain in the United States Army Medical Corps. He was then assigned to Evacuation Hospital No. 30 and promoted to major in September and arrived in France with his unit on Armistice Day. In 1925, he accepted a full-time position at the Massachusetts General Hospital as chief of the West Surgical Service and associate professor of surgery at Harvard Medical School, later becoming John Homans Professor of Surgery. He held these positions until 1931, when he was obliged to withdraw from active practice because of ill health.

He was a member of the Massachusetts Medical Society, American Medical Association, American College of Surgeons, American Surgical Association, Southern Surgical Association, and Society of Clinical Surgery.

Three sons survive.

RILEY — Charles A. Riley, M.D., of Newton, died January 30. He was in his sixty-third year.

Dr. Riley received his degree from the Jefferson Medical College of Philadelphia in 1905. He was a member of the staff of the Brooks Hospital and a consultant for the public-health services in Boston and Newton. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son and a daughter survive.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

HYLAN — N. Wicker Hylan, M.D., a major serving as flight surgeon with the Air Corps of the Army of the United States in England, was killed on January 28 as the result of an aircraft accident. He was in his thirty-seventh year.

Dr. Hylan received his degree from Tufts College Medical School in 1935. He formerly practiced in Derry and went overseas in June, 1943. He was a member of the New Hampshire Medical Society.

His widow, four children, a sister and two brothers survive.

THE USE OF REFRIGERATION IN AMPUTATIONS AND PERIPHERAL VASCULAR DISEASE*

E. EVERETT O'NEIL, M.D.†

BOSTON

DURING the last three and a half years, an attempt has been made at the Boston City Hospital to evaluate the role of reduced temperatures in the treatment of various types of peripheral vascular disease. Particular interest has been directed toward the employment of refrigeration as an anesthetic agent in amputations of the extremities for gangrene due to primary arterial disease. In addition, the effects of localized chilling of tissues in states of impending ischemia, due to sudden arterial occlusion, sepsis and venous thrombosis, have been observed.

The use of cold as a therapeutic agent is not new. Ice applications and cold compresses for the relief of pain and reduction of inflammation are as old as medicine. Within recent years, newer concepts of refrigeration have been developed. The familiar work of Fay and his associates in reducing temperatures over long periods of time in patients suffering from cancer emphasized that a lowered metabolic state, comparable to hibernation in lower animals, is possible in human beings. Whatever the value of these studies so far as any positive attack on the broad field of malignancy is concerned, they pointedly demonstrate that tissue metabolism can be slowed to a degree hitherto not thought possible. A more recent development, and the one that this paper is particularly concerned in describing, has been prompted by the observations of Allen¹ on the use of refrigeration in diabetic or arteriosclerotic gangrene or both.

Experimental Evidence

There is ample evidence that when the extremities of animals become totally ischemic as the result of the deprivation of blood supply by a tourniquet, exposure to room temperature or to an increased temperature results in rapidly progressive

tissue necrosis. It has further been observed that the reduction of temperature enables limbs to survive for a much longer period of time. Brooks and Duncan,² for example, noted that a rat's tail became gangrenous within four hours after ligation at a temperature of 40°C. When, however, the temperature was reduced to approximately 4°C., the survival period was extended to as long as four days. Allen³ observed that the hind legs of rabbits, cats and dogs survive asphyxia for thirteen to fifteen hours at room temperature. When the temperature is reduced and maintained at approximately 2 to 4°C., the dangers of ligation are greatly diminished. Under these conditions, limbs showed a survival period of fifty hours or longer. Furthermore, the phenomena of shock, thrombosis, infection and injury to blood vessels and nerves were markedly inhibited.

Clinical Considerations

The results of animal experimentation obviously suggest imitation in human beings. It thus appears that the use of ice as an anesthetic agent might be of particular value in a group of poor-risk patients, in whom mortality in major amputations has always been appallingly high. The type of patient found in the clinics of municipal institutions—undernourished, neglected, discouraged, often with an advanced state of peripheral arterial insufficiency, seen for the first time with rapidly spreading gangrene and sepsis, and with histories of previous cardiac and cerebral accidents—immediately suggests the likeliest candidates for this form of therapy. In these patients, spinal or general anesthesia, with additional operative shock, are all too frequently the factors militating against recovery. On the other hand, it is probable that, except in rare cases, the method of refrigeration has little to offer in groups of selected patients watched carefully by organized groups of physicians and surgeons. In these cases, anesthesia probably seldom contributes to mortality.

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1943.

†Visiting surgeon, Boston City Hospital, clinical professor of surgery, Boston University School of Medicine

Tourniquet and Refrigeration

The method under discussion, as has been stated above, is essentially one of combined ligation by means of the tourniquet and refrigeration. The application of the tourniquet itself is of considerable importance. Rubber tubing, 10 to 12 mm. in diameter, is the best material for ligation. Allen¹ has demonstrated that wide bands, such as an Esmarch bandage, by traumatizing wide masses of tissue, contribute to a greater degree of secondary shock than do narrow bands. Two turns of the tourniquet are made at the selected site, and the tubing is held in place by a clamp or knot, care being taken that the skin is not pinched. The tourniquet is applied as tightly as possible. As a preliminary measure,

thermometer, held against the skin from time to time, will enable the leg to be kept at the proper temperature level.

In the average case, in our experience, it takes between two and two and a half hours to produce sufficient anesthesia to allow a painless amputation. In a thin, emaciated, arteriosclerotic limb, anesthesia is necessarily attained more quickly than in the extremity of a young, muscular patient who requires an amputation because of trauma.

No attempt should be made to hasten a refrigeration amputation for fear of too long constriction of the limb by a tourniquet. In several of our cases the tourniquet has remained on for ten to twelve hours, and in no case has there been any interference with

FIGURE 1. Leg from Tourniquet to Toes Encased in Cracked Ice and Surrounded by Rubber Sheeting.

The lower leg and foot are exposed for demonstration purposes.

several ice bags are placed at the ligation level for a few minutes, in order to minimize any discomfort incidental to the placing of the rubber tubing. Refrigeration is immediately begun.

In the case of a low thigh amputation (Fig. 1), the entire leg and thigh up to the tourniquet site are surrounded by cracked ice encased in rubber sheeting or in a special container* built for the purpose (Fig. 2). A skin temperature maintained at about 8 to 10°C. has been found most desirable, assuring that the part is chilled and not frozen (Fig. 3). It must be emphasized that refrigeration is not freezing, and the terms should not be confused. Tests by an ordinary house or laboratory

subsequent primary wound healing of the stump. The usual criticism of undue trauma to blood vessels from a tourniquet does not appear to be warranted under conditions of refrigeration. Moreover, in certain cases we have intentionally waited longer than the customary anesthesia period in order that the patient's general condition might improve. It has been apparent that reduced temperatures have definitely promoted the comfort of the patient.

As a rule, little if any preliminary medication is needed, unless the patient is apprehensive or nervous. Indeed, the improvement of the mental and physical state after refrigeration has been initiated is dramatic.

Operation and Aftercare

When the desired anesthesia has been reached, the patient is moved, with the ice container, to the

*This container was designed by Dr. Andrew Webster, intern on the Third Surgical Service, Boston City Hospital, who has assisted in this study. The Therm-O-Rite Products Company, Buffalo, New York, has developed an electrically operated, thermostatically controlled refrigeration unit that does away with the obvious difficulties associated with ordinary refrigeration methods.

operating room and placed on the table. The container is removed and the limb is prepared for operation. The incision is made 10 to 15 cm. below the level of the tourniquet (Fig. 4). The type of amputation should be the simplest. Our preference is for a circular amputation, with staggering of skin, muscle and bone layers and without the formation of flaps, leaving the skin incision dog eared on each side. This method assures a comfortable and ultimately a good-looking stump. No drains are ever used (Fig. 5). The omission of drainage is as essential to primary healing in the refrigerated stump as it is in elective amputations done under any of the commoner methods of anesthesia.

It is our conviction that the guillotine amputation with no attempt at closure is preferable to the em-

limb at a lower limit than ever before thought practical — for example, 5 to 7 cm. above the ankle. Since the saving of life and not the correct fitting of a prosthetic appliance is the purpose in many older patients, this procedure is a reasonable one. It is recommended in selected cases.

Patients undergo refrigeration amputations without pain and without shock. Pulse and blood-pressure levels are not changed by the operative procedure. The usual postoperative discomforts — nausea, vomiting, and pain — are not experienced. The following case reports illustrate these facts.

CASE REPORTS

CASE 1. S. G., a 10-year-old boy, suffered a compound fracture of both bones of the left forearm on October 4, 1941, when he fell while playing in a stable. He was operated on shortly after admission to the hospital. The usual procedure

FIGURE 2. Home-Made Wooden Container.
This box is much easier to handle than rubber sheeting.

ployment of drains and that in the presence of rapidly ascending infection it is the procedure of election. The tourniquet is released just prior to closure of the wound. Circulation returns promptly, and there is bleeding in proportion to the vascular supply of the limb. It will be observed that there is no thrombosis within the blood vessels and that the blood is in its normal fluid state. The muscle bundles appear healthy and a somewhat brighter red than usual, comparable to the color of meat subjected to icebox temperature.

In this series of cases, the traditional amputation sites have been adhered to fairly closely. It has been suggested,⁴ however, and, we believe, with merit, that lower amputation levels in the leg may be selected. Despite the minimal circulation present in arteriosclerotic extremities, refrigeration, by reducing tissue metabolism and lessening the demands on the available blood supply, permits removal of a

of treating compound fractures was assiduously carried out, including wound débridement, introduction of sulfanilamide powder into the wound and prophylactic tetanus-gas gangrene antitoxin. Three days later, the temperature was 104.2°F. and the pulse 170 (Fig. 6). The wound was inspected and the arm was found to be swollen, with no pulse at the wrist and crepitation of the tissues. A diagnosis of gas-bacillus infection was made. The wound and adjacent soft tissues were opened widely, irrigations of hydrogen peroxide were instituted, and therapeutic doses of gas-gangrene antitoxin (10,000 units every 4 hours) x-ray and sulfanilamide were given. Despite all treatment, the infection rapidly spread upward and the arm became gangrenous. Permission for amputation was refused by the patient's parents. Four days later, he was practically moribund, with a rectal temperature of 103°F., a pulse of 160 and an extension of the infection into the axilla and anterior chest wall. Consent for amputation was finally obtained.

A tourniquet was applied to the upper arm just above the grossly sloughing area, and the extremity below the tourniquet was packed in ice. Within 2 hours, the patient's condition improved remarkably. He became brighter and less toxic appearing, and showed a drop in temperature and pulse rate. Because of this slight improvement, amputation was delayed for approximately 20 hours more, in the hope

that further improvement would enhance the chances of recovery (Fig. 7). At that time a quick guillotine high-arm amputation was done in the patient's bed. He stood the operative procedure well. Convalescence was entirely uneventful, and he was discharged home in 3 weeks.

The refrigeration amputation was probably not the only factor in this patient's recovery. It seems certain, however, that had any other anesthetic agent been used he would not have survived.

CASE 2. J. B., a 71-year-old man, was admitted to the hospital on July 26, 1941, with a diagnosis of fracture of the left patella. Five days later, under spinal anesthesia, an open reduction was performed with silk-suture technic. Six days later, sepsis in the wound was observed and drainage was instituted. Improvement occurred for a time, but sepsis then progressed, and wide incision and exploration were done, again under spinal anesthesia, on November 17.

FIGURE 3. Temperatures Taken at Skin, Muscle and Bone Levels in the Amputated Stump following Refrigeration.

This figure demonstrates that cold penetrates to sufficient depth within two or three hours to ensure adequate anesthesia for amputation.

Necrotic fragments of the patella were removed and it was noted that the joint cartilage was completely destroyed. X-ray films showed destruction of the upper end of the tibia and the lower end of the femur. The patient ran a stormy postoperative course, including pneumonia at the bases of both lungs, and continued to run a spiking temperature between 101 and 103°F. He went downhill rapidly, and a refrigeration amputation of the thigh was decided on. After 4 hours of refrigeration, the patient's condition did not improve and death seemed imminent. Amputation was postponed. After another interval of 3 hours (7 hours of refrigeration), his condition seemed favorable enough to warrant operation.

Thigh amputation was done painlessly and without any perceptible change in the pulse or blood pressure. The stump was left open and traction sutures were applied to the skin. The postoperative course was uncomplicated. No further plastic procedure was necessary on the stump, and the patient left the hospital in 6 weeks.

This case is typical of the old, bad-risk patients who, because of sepsis and arterial insufficiency, withstand poorly major operative procedures on the extremities.

Postoperative management is predicated on the principle that temperatures may be reduced or elevated according to the patient's needs. The temperature of the stump is allowed to return to normal by the gradual withdrawal of the ice bags placed about the stump. If, on the other hand, there is any tendency to sloughing or infection of wound edges, further reduction of tissue metabolism to a level for which the existing blood supply is adequate should be initiated.

Healing

Most wounds from refrigeration amputation when tightly closed heal per primam, and the percentage of first-intention healings is comparable to that after similar operations done under other anesthetics. It is to be emphasized, however, that refrigerated incisions heal more slowly than others, because of the known tendency of cold to inhibit agglutination of wound surfaces. Sutures should therefore not be removed from wounds for fifteen to twenty days. Raising the temperature of the stump as rapidly as possible promotes rapid healing, but this is not justifiable because of the risk of incurring sloughs. Slow healing is better than no healing at all.

Clinical Data

In the ten-year period from 1930-1939, there were at the Boston City Hospital 162 cases of major gangrene of the extremities from different causes that were deemed inoperable, either because of the spread of the disease itself or because of other factors, such as old age and cardiorenal, cerebral or other complications (Table 1). The mortality rate was 100 per cent. It was believed that if a certain percentage of lives could be salvaged from a comparable group of bad-risk patients, the refrigeration method would be decidedly worth while. In addition, the mortality rate on 270 cases of major gangrene operated on at this hospital between 1930 and 1939 was 53 per cent. Although no attempt is made here to analyze this high mortality figure, and although it is certain that many poor-risk cases were included in the group, it is our conviction that it is excessively high.

Fifty-four patients were refrigerated. Of these, 50 came to amputation and 4 died before operation. The latter were moribund on entry. The ages

TABLE 1. Results in Cases of Major Gangrene, with and without Amputation and with and without Refrigeration.

TYPE OF CASE	NO. OF CASES	NO. OF DEATHS	PERCENTAGE MORTALITY
Unoperated cases, with complications (1930-1939).....	162	162	100
Operated cases, with and without complications (1930-1939).....	270	142	53
Unoperated cases, with refrigeration (1940-1943).....	4	4	100
Operated cases, with refrigeration (1940-1943).....	50	16	32

ranged from fifty to ninety, with 1 patient in the second decade, 8 in the sixth, 17 in the seventh, 24 in the eighth and 4 in the ninth. Forty-nine patients suffered from advanced arteriosclerotic gangrene with complications of diabetes and sepsis (16 cases) recent cerebral accidents and cardiac failure (2 cases) or other serious infirmities.

The immediate salutary effect of chilling of tissue on the more prominent signs and symptoms was most striking. Relief of pain was observed in every case and without the aid of the customary medica-

tion It is well known that sudden arterial occlusions, as from embolism, are most painful and that great discomfort persists for many hours after the initial obstruction. It has been in this group that the relief of pain has been most dramatic. Shock has always been an outstanding and disturbing feature of thigh amputations, both during and after operation. In addition to operative trauma, general and spinal anesthesia, particularly the latter with its frequent attendant fall in blood pressure, contribute greatly to secondary surgical shock. This phenomenon is not observed in refrigeration operations

from the figure of 53 per cent on operated cases during the ten-year period 1930-1939. In a series of 50 unselected cases in another municipal hospital, Crossman et al,⁵ have shown a mortality of 13 per cent under the refrigeration method, with only 1 death in the last 30 cases, a mortality of only 3 per cent. It may be pertinent to apply the tourniquet-refrigeration method as a routine procedure in all cases coming to major amputation in large municipal institutions.

The causes of death in this series are interesting, since most of the fatalities occurred after the pa-

FIGURE 4 Simple Circular Amputation below the Tourniquet Site. The tourniquet remains on during operation and is removed just before closure of the fascia.

There was little if any pulse or blood pressure change in this series, in fact, shock was practically absent in 50 cases. The progress of gangrene and sepsis was notably inhibited in 48 cases by the application of cold. In several of these cases a tourniquet and refrigeration were applied for as long as twelve hours without progress of infection or gangrene and with first intention healing following amputation. At first, doubt was entertained as to the effects of low temperatures on wound healing and breaking down of the operative site was expected. For this reason, the first few amputations, because of gangrene and sepsis, were done by the guillotine method, with secondary closure performed later. Subsequently, all wounds were tightly closed except those in which there was an unusual amount of rapidly ascending infection.

In 50 cases of amputation, there were 16 deaths, a mortality of 32 per cent (Table I), and a salvage, in terms of 1930-1939 figures for unoperated cases, of 68 per cent. In addition, by this method there has been a reduction of 21 per cent in mortality

patients were over the effects of their operation, with stumps adequately healed, and were sitting up or out of bed or ready to be discharged.

Two patients died from gas-bacillus infection in the stump. These were among the early patients refrigerated and represented consecutive cases from the same ward. They had not been given preliminary anti gas bacillus serum. At the present time, not only does every case get prophylactic polyvalent anti gas-bacillus serum, but sulfanilamide is put in the wound before closure. The other 14 deaths were due to various manifestations of cerebrovascular accidents, sudden cardiac failure or pulmonary embolism.

Despite the lack of apparent relation to the anesthetic agent, these deaths must statistically be held against the operative procedure.

In a more recent study of 33 consecutive cases of major gangrene at the Boston City Hospital, taken as they came to the surgical services, including both good and bad risks, there was a total of 4 deaths, a mortality of 12 per cent — a decided contrast, al-

though in a much smaller series, to the 1930-1939 mortality rate of 52 per cent.

Refrigeration without Amputation

Local chilling of tissues without application of the tourniquet was attempted in a series of cases in which there was some factor of circulatory insufficiency that had not progressed to the point where loss of the limb was indicated. The method used was either the application of ice bags or immersion of the limb in crushed ice for several hours. It was hoped that the lowered oxygen demands of the part thus affected might avert impending gangrene, inhibit sepsis or retard thrombosis. This

This case suggested the application of reduced temperature to all extremities in which there were progressive occlusion of the peripheral arterial trunks and signs of imminent gangrene. At the present time, all cases of arterial insufficiency in the extremities, from whatever cause, are treated by the application of cold, and no longer by the old, familiar heat cradle encasing the time-honored 50-watt bulb, which so often resulted in the rapid spread of the gangrenous process. In this group may be mentioned vascular insufficiency brought about by arterial thrombosis or sudden arterial occlusion due to emboli, in which the time interval of four to five hours for doing a successful arterial embolectomy has passed, and frostbite of whatever

FIGURE 5. *Wound Closed without Drainage.*

The sutures should remain in place for fifteen to twenty days because of delay in wound healing due to cold.

series is too small for the results to be convincing, but it nevertheless suggests certain important trends in the therapy of these conditions.

In some of these cases, the results were extremely gratifying; in others, they were frankly disappointing. On the encouraging side was a moderately advanced case of scleroderma, with deep infection of the fascial space in the hand. The employment of hot compresses and hot soaks resulted in a rapid spread of sepsis, with marked bleb formation. Since a state of deficient blood volume in the sclerodermic extremity was being dealt with, it became evident that increased oxygen demands engendered by the application of heat were causing a progressive spread of infection. A reduction in temperature, by burying the forearm and hand in ice and alternating this procedure with ice bags, produced a gradual but definite recovery.

severity. In this connection the emphasis that has been put by Webster, Woolhouse and Johnston⁶ on the effect of reduced temperature in the treatment of immersion foot deserves mention. These observers noted a tremendous tissue reaction when patients suffering from immersion feet were exposed to ordinary room temperatures. There was edema, ecchymosis and bleb formation of the skin, suggestive of the reaction of feet with impaired blood supply that are developing gangrene. Reduction of temperature to 6°C. below normal skin temperature by the application of ice bags was the best single therapeutic measure used in combating this condition.

In the presence of frank gangrene of the extremities, with or without sepsis, refrigeration definitely retards the progress of gangrene and infection. In no cases in our experience, however, has

reduction of temperature averted amputation when devitalization of a part had once occurred. It has

Several patients with deep venous thrombosis of the lower extremities, all candidates for ligation and

after refrigeration, gangrene progresses rapidly. A return to decreased temperature slows the process.

A local chilling of the tissues. All improved without further treatment. This observation is not par-

ticularly convincing, since many such cases improve with rest alone. It may be of value, however, in suggesting that prolonged cold, without freezing, inhibits thrombosis. Our preference in the treatment of deep venous thrombosis, we hasten to add, is still for interruption of the proper deep venous channels.

Refrigeration has been suggested as a valuable adjunct to the treatment of various injuries and burns. The advantages of cold in preventing toxic absorption, inhibiting bacterial growth and reducing pain, shock and edema seem to make this method desirable in traumatic cases. Its influence in military surgery, particularly under conditions of active warfare, appears to be of inestimable value. Its application is strongly urged.

SUMMARY AND CONCLUSIONS

The use of refrigeration as an anesthetic agent in major amputations of the extremities is a sound surgical procedure. It is particularly applicable to poor-risk cases, since it inhibits shock, relieves pain, retards infection and thrombosis.

A series of 50 bad-risk patients treated by the tourniquet-refrigeration method showed a marked reduction in mortality under that of a comparable series either untreated or treated by some other method. A later series of 33 patients, both good and bad risks, showed a marked reduction in mortality after refrigeration amputation.

Further possibilities in the use of reduced temperatures in the treatment of peripheral vascular disease and of injuries and in military surgery have been discussed.

I am indebted to Dr. George Miller, resident surgeon on the Third Surgical Service, Boston City Hospital, for his assistance in compiling the data used in the preparation of this paper. 270 Commonwealth Avenue

THE TREATMENT OF PULMONARY EDEMA DUE TO GAS POISONING IN WAR AND IN CIVILIAN LIFE*

With Special Reference to the Use of Positive-Pressure Respiration

ALVAN L. BARACH, M.D.†

NEW YORK CITY

THE purpose of this paper is to outline a tentative program of treatment for patients who develop edema of the lungs following exposure to irritant gases.

For the most part, pulmonary irritants are considered acid gases, since they owe their physiologic effect to the fact that they are acids or behave like acids under the conditions of their use. They include hydrogen chloride, bromide and fluoride, chlorine, fluorine, bromine, sulfur dioxide and certain oxides of nitrogen, as well as phosgene, di-phosgene and chloropicrin. There are other less common pulmonary irritants such as ammonia and formaldehyde. The carbonyls are also included in this group because of their property of depositing finely divided particles of metal in lung tissue, thus inducing an intense pulmonary irritation and edema. The properties of these substances determine their behavior in the body. Thus, their solubility in water is a determining factor in the location of their action. Highly soluble gases, such as chlorine, ammonia and sulfur dioxide, exert their primary effects on the upper-respiratory tract and, if exposure has taken

place to low concentrations or for not too long time, the damage may be confined almost entirely to the nose and throat. Exposure to higher concentrations or for a longer period of time results in characteristic edema of the lungs, without extensive necrosis of the upper respiratory tract. The chief injury associated with inhalation of phosgene is ascribed to be in the lungs, in which congestion and widespread edema ultimately develop.

Chlorine and phosgene are sometimes employed in war gases for their destructive effect, but they also have been known to cause pulmonary edema in civilian life as the result of disasters or industrial accidents. For example, when carbon tetrachloride (Pyrene) is used in fire extinguishers in enclosed spaces, it may be sprayed on hot metal, with a resultant liberation of phosgene. Edema of the lung may thus take place if the concentration of the phosgene evolved is such as to cause damage to the lining of the respiratory passages as well as to the pulmonary epithelium.

Phosgene is a colorless gas at temperatures above 8°C., with an odor of musty hay. It is soluble in water, and hydrolyzes to hydrochloric acid and carbon dioxide. Since there is little immediate irritation to the larynx and trachea, the gas may reach the lungs in high concentrations. Thrombosis of the blood vessels, concentration of blood in the per-

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 26, 1943.

monary capillaries, edema in the alveoli and in the alveolar septa and rupture of the alveoli constitute the main pathologic effects. If the patient survives the pulmonary edema, bronchopneumonia frequently follows and may be the cause of death.

In general, the pathologic condition found after inhalation of irritating gases is that of intense congestion and inflammatory edema, followed by a cellular exudate, with a varying amount of necrosis of the lining membrane of the respiratory passage. If death does not take place, there may be organization of the exudate within the alveoli and bronchi, with the production of bronchiectasis, pulmonary fibrosis and perhaps chronic suppurative lesions. The variations in pathologic effects exercised by the several gases have been fully described by Winternitz and his associates¹⁻⁵; Haggard⁶ and Henderson and Haggard⁷ have pointed out the similarity in toxicologic action of all the respiratory irritants and have stressed the difference in symptomatology as due to the location of their action and the relative solubility of the irritating gases. A gas that is highly soluble in water is readily taken out of the inspired air by contact with the first moist tissue it reaches, and therefore the upper respiratory tract bears the brunt of action. On the other hand, a gas with a low solubility in water is slower to liberate its irritant principle, and the most important damage usually takes place in the pulmonary epithelium. Carlisle⁸ has listed the following gases that have resulted in pulmonary edema in the course of industrial accidents: the oxides of nitrogen, phosphorus oxychloride, phosphorus pentachloride, phosphorus trihydrochloride, methyl bromide, chlorine, cadmium and dust from certain alkalis.

Sulfur dioxide is an effective refrigerant but is a respiratory irritant that has been said by Hamilton,⁹ Norris and Landis,¹⁰ Gordon¹¹ and Kehoe et al.¹² to be the cause of deleterious effects, although no lasting harm after exposure was observed by McCord.¹³

The symptoms depend on the solubility of the gas, as mentioned above. In some cases cough and tightness and pain in the chest are followed by shortness of breath and expectoration of seromucus, such as after exposure to the fumes of chlorine, nitric acid, ammonia and chlorpicrin. In other cases, such as after exposure to phosgene, the patient may reveal no symptoms for two to four hours except watering of the eyes and catching of the breath. Later, tightness of the chest, painful coughing and the characteristic symptoms of edema of the lungs may manifest themselves, with moist rales and bloody or frothy sputum. If the concentration of phosgene is moderately high, symptoms of pain in the chest and coughing may assert themselves soon after exposure.

Kehoe¹⁴ has mentioned four types of effect of exposure to irritant gases. The effect of exposure to extremely high concentrations may be immediate

death from anoxia due to direct damage to the respiratory membranes, rendering them impermeable to normal respiratory gases. Rapid absorption of the poison may be the chief factor in death by producing circulatory collapse (vagus shock). Differing only in degree from the above is an exposure to a high concentration of an irritant gas that results in extensive damage to the pulmonary and upper respiratory tissues, including acute hyperemia, and destruction of tissue (coagulative necrosis). If death does not take place promptly, acute emphysema of the lungs, with general acute interstitial edema, ischemia and coagulation necrosis, may result, with death the ultimate outcome. The moderate nature of a pulmonary injury makes possible an opportunity for survival. Irritative effects in the upper respiratory tract and acute pulmonary edema may be present, with threatened asphyxia or later complications, such as bronchopneumonia. Lastly, mild exposure to respiratory irritants for comparatively short periods may result in injury mostly limited to irritation of the eyes and upper respiratory tract, with redness and lacrimation, coughing, sore throat, huskiness, loss of the voice, nosebleed, moderate chest pain and excessive coughing. Recovery may take place with little or no treatment, but in some cases the condition progresses to such an extent that the patient is placed in the category described above.

Since this discussion is confined to the treatment of pulmonary edema, the chronic effect of gas poisoning and the manifestations of chronic gas poisoning will not be considered. The nature and severity of edema of the lungs after exposure to gas poisoning is difficult to predict, since the pathologic condition is subject to considerable variations depending on the gas concerned as well as on its concentration and the length of exposure. The onset of pulmonary edema may be prompt, or it may be delayed for as long as twelve hours. In the upper respiratory tract an inflammatory reaction may take place with a serosanguineous discharge; later, ulceration and hemorrhage may manifest themselves. In certain cases the bronchi show ulcerations and necrosis and plugs of debris obstruct the smaller air passages. The lungs may be filled with edema, and the trachea as well. A watery and at times serosanguineous fluid may be present, with, later, a purulent or fibrinopurulent exudate. Edema of the alveolar cells and interstitial tissues, with coagulation necrosis, hemorrhage, thrombosis and infarction of the blood vessels, may be present in varying proportions at different sites of the lungs. Damage is likely to be spotty rather than general. This may be caused to some extent by bronchial obstruction, due either to inflammation or to bronchial spasm, which limits the passage of contaminated air to certain parts of the lungs. Both petechial and confluent hemorrhages take place. Large or small areas of deeply congested lung tissue are seen at autopsy,

with a thin, sanguineous fluid dripping from the surface. If death takes place at a later stage of the development of pulmonary edema, chronic bronchitis, bronchiectasis and abscess of the lungs may be found.

As a result of swelling of the alveolar cells, the absorption of oxygen at atmospheric pressure proceeds at a slower rate than normally and unoxygenated blood passes into the aortic stream. The narrowing of the smaller bronchi results in incomplete ventilation of some of the alveoli, with accentuation of anoxia. Finally, the presence in the alveoli and the respiratory passage of serum and mucus further complicates ventilation of the alveoli.

In cases in which there is constriction of the bronchi, due to spasm and inflammatory swelling of the mucous membrane, an increased respiratory effort takes place, with a resultant increase in the negative pressure within the lung during inspiration. Any increase in negative intrapulmonary pressure tends to aggravate edema of the lungs by producing a suction action on the pulmonary epithelium. The increased ventilation engendered by anoxia is apt to be followed by a lowering of the carbon dioxide tension in the blood, the acid-base equilibrium shifting to the alkaline side. In severe asphyxia, however, acidosis takes place, the low pH being due to incompletely oxidized acid metabolites.

When pulmonary edema has been present for a considerable period of time, the loss of serum in the lungs results in concentration of the blood, and the diminished blood volume and increased viscosity promote stasis and capillary thrombosis. This circumstance is an additional factor that makes for tissue anoxia and ultimately throws an increased burden on the heart, owing to the increased resistance in the pulmonary circuit. Death may ultimately take place from right-sided heart failure, peripheral circulatory failure or bronchopneumonia.

The routine prescription of rest, warmth and inhalation of oxygen-enriched air is helpful to a certain percentage of patients. The inhalation of air with a high percentage of oxygen, such as 50 to 70 per cent, diminishes the severe anoxia in cases of outspoken pulmonary edema and this protects the patient from a cardiorespiratory failure that might otherwise ensue. Furthermore, the volume of ventilation is diminished under these circumstances by inhaling air with a high oxygen concentration and in this way the pathologically elevated negative intrapulmonary pressure is diminished and the suction effect of a high negative pressure on the lungs is prevented.

In many cases of pulmonary edema treated with rest, warmth and the inhalation of air with a high oxygen concentration, the passage of serum from the capillaries into the alveoli continues and drainage through the respiratory passageway is impeded, with the ultimate development of bronchopneumonia

and death. The administration of positive pressure to combat edema of the lungs produced by gas poisoning was suggested by Barach, Martin and Eckman¹⁵ in 1938 in a paper dealing with the therapeutic advantages of positive pressure in the treatment of clinical pulmonary edema. Mention was there made of a case of edema of the lungs described by Norton¹⁶ in 1897 in which a rapid clearance of the edema took place with the use of the Fell-O'Dwyer forced-respiration apparatus. Although a theoretical discussion of the mechanism was not given in Norton's report, the clinical result was carefully described and was unmistakably the result of the introduction of a laryngeal tube and the application of forced respiration under positive pressure. In previous studies on the application of positive pressure in the treatment of irritant pulmonary edema due to gas poisoning have been reported.

The use of positive pressure for the treatment of clinical pulmonary edema was suggested by Plesch and an apparatus for providing it was used by Poulton¹⁸ in cases of paroxysmal dyspnea—called "cardiac asthma"—and of bronchial asthma. No benefit was obtained when there was generalized heart failure.

Barach¹⁹ and his colleagues developed an apparatus for the administration of positive pressure, originally for the treatment of bronchial obstruction in intractable asthma and obstructive lesions of the respiratory passageway. These comprised a mask with a closed-circuit apparatus, a hood that fitted over the patient's head and made closure at the neck and a mask in which the patient breathed during expiration against resistance, provided by exhalation at first through a rubber tube placed in water to a depth of 3 to 6 cm., and later through a variably narrowed orifice attached to the mask. The methods of applying positive pressure were found to be effective in many severe cases of edema of the lungs occurring during the course of pneumonia and acute failure of the left ventricle.

In 1909, Emerson²⁰ showed that pulmonary edema produced by the intravenous injection of adrenalin into rabbits could be consistently removed by artificial respiration through a tracheotomy tube in which the lungs were gently distended and then allowed to collapse. In 1917, Auer and Gates²¹ confirmed these results and showed that tracheal stenosis accentuated the edema caused by adrenal congestion and edema of the lung as the result of tracheal stenosis were shown by Moore and Bing to be due to obstruction during the inspiratory cycle. Kernan and Barach²² confirmed these observations and showed that expiring against a pressure of 4 to 5 cm. of water created no significant change in the lungs, whereas inspiring against a negative pressure of 4 to 6 cm. caused congestion and pulmonary edema in the lower part of both lungs, with areas of emphysema at the periphery. The negative intrapleural pressure became steadily elevated with

animals were made to inhale through a constricted orifice. This elevation was decreased by the inhalation of a helium-oxygen mixture or by the administration of positive pressure during inspiration. The significant factor in the production of pulmonary congestion and edema due to narrowing in the respiratory passage appeared to be the pathologically elevated negative intrapleural pressure, which resulted first in an increase in pulmonary blood flow and later in a direct cupping action on the pulmonary capillaries. In experiments on animals, Barach, Martin and Eckman¹⁵ showed that edema of the lungs produced by intravenous injection of adrenalin could be prevented by inhalation of air under positive pressure, which raised the intrapleural pressure toward the atmospheric pressure during expiration. In this experiment it was demonstrated that no heightened negative pressure existed in the intrapleural space, and that the effectiveness of positive pressure was due to the direct opposing pressure on the capillary epithelium in the lungs of a physical force that tended to counteract the internal hydrostatic pressure in the pulmonary capillaries. Another influence was that the positive pressure retarded, to some extent, the inlet of blood into the right side of the heart.

It may be mentioned at this point that Meltzer²⁴ in 1878, said that the origin of pulmonary edema was due to a disproportion between the working power of the left ventricle and that of the right ventricle of such a character that, the resistance being the same, the left side of the heart was unable to expel in a given unit of time the same quantity of blood as was the right side.

The effect of respiration under positive pressure of 3 to 10 cm. of water in normal persons and in patients with congestive heart failure and asthma has been studied by me and my colleagues.^{15, 18, 23} The venous pressure was consistently elevated. During the application of a pressure of 6 cm. the venous pressure was elevated 2 to 3 cm. The circulation time in normal young adults was slightly prolonged, but in patients with heart disease the slowing was as much as ten to fifteen seconds. Although prolongation of the circulation time did not occur in all cases, the change when it took place was more marked in cardiac patients than in normal persons, in whom the prolongation when breathing against a positive pressure of 6 cm. averaged three and a half seconds. In a normal adult the effect of breathing against a positive pressure of 6 cm. resulted in an increased amount of air in the lungs, — approximately 400 cc., — with a lowering of the midposition of the lungs and a lengthening of the vertical diameter of the chest. The only contraindication to the use of positive-pressure respiration noted by Barach, Martin and Eckman¹⁵ was that of peripheral circulatory failure. Since in shock a deficient return of blood to the right side of the heart is already present, the high intrapulmonary pressure

produced by inhalation of air or oxygen under positive pressure may further prevent the customary entrance of blood into the right auricle. The clearing of pulmonary edema in clinical cases of edema of the lungs was later confirmed by Boothby, Mayo and Lovelace²⁵ and others.²⁶

In summary, the effects of positive-pressure respiration include an increased intrapulmonary pressure, which lowers the pathologically elevated negative pressure in the lung during respiratory obstruction (Fig. 1); an increase in systemic venous pressure amounting to 40 to 50 per cent of the applied pressure; a prolongation of the circulation time, which is notably more marked in patients with congestive heart failure than in normal subjects; an increased volume of air in the lungs, with a lowering of the midposition of the lungs and an increase in the vertical diameter of the chest; and a decrease in the transverse diameter of the heart, shown in roentgenograms of rabbits' hearts.

The favorable results of the administration of oxygen and helium-oxygen mixtures under positive pressure in the treatment of ordinary cases of edema of the lungs suggest that it would be valuable in the treatment of irritant gas poisoning.¹⁸ In a personal communication, Carlisle⁶ has reported that the administration of oxygen under an expiratory positive pressure of 1 to 6 cm. of water is the most effective method of treating and preventing pulmonary edema due to irritant gases. No patient exposed to lung irritants has been lost since this procedure was adopted. Over 300 cases of such exposure have been treated, and at least 25 manifested signs of edema.*

The technic of applying positive pressure may consist of the use of the hood designed for the treat-

*Since this paper was prepared, Carlisle has made the following statement (*J. A. M. A.* 123:947, 1933):

Without significant bronchiolar obstruction and before advanced

from our own experience that the use of the 1 to 100 epinephrine solution combined with the administration of oxygen under positive pressure of 1 to 6 cm. of water may be recommended for active treatment of the advanced stages of pulmonary edema caused by certain noxious gases. In our experience this has been a far more effective method of handling frank pulmonary edema than any of the procedures hitherto suggested. We find that on check of our records for the past year and a half, we have had 316 cases in which only this method of treatment has been employed.

Boothby, Evans (*New York State J. Med.* 43:2303-2305, 1943) has commented on the use of positive pressure in treating the irritant pulmonary edema that developed in victims of the Cocoanut Grove Fire in Boston. He states that good results were obtained with the employment of oxygen under positive pressure and that the results in 4 cases were "rather spectacular."

The following notes on a case of irritant pulmonary edema were kindly transmitted to me by Dr. E. A. Rovenstein, of New York City, who treated a patient with positive pressure. The significance of this case is comparable with the application of an expiratory positive pressure of 5 cm. was followed by a swift clearing of edema, and seemed specifically responsible for recovery.

A middle-aged woman admitted in the early morning on February 19, 1943, had been exposed to fumes of a chemical (undetermined, but may have been dimethyl sulfide). Epistaxis was about 9:00 p.m. the evening before, with no symptoms for a couple of hours. Lacerimation and burning of the eyes and throat were noted. Later the patient became short of breath. On admission she was dyspneic and had severe pain, copious secretions and acute cyanosis. The respiratory rate was 30 to 40, and the heart rate 120. Her condition rapidly became worse.

Oxygen was administered through the nasopharynx. An hour later there were obvious pulmonary edema, extreme cyanosis, marked venous engorgement and severe pain. Her condition was rapidly becoming alarming. An O. E. M. positive-pressure mask was adjusted at 5 cm. pressure, the result was dramatic, and within 15 to 20 minutes the edema had cleared. A phlebotomy (200 cc.) was completed after improvement was noted from oxygen therapy. The subsequent recovery was essentially uneventful.

ment of obstructive dyspnea, in which a positive pressure of 3 to 6 cm. is applied, during both inspiration and expiration. This method is the most comfortable and effective one for positive-pressure breathing. Dyspnea is relieved, since the pressure during inspiration results in a swift lowering of the intrapleural and intrapulmonary negative pressure and, during expiration, in a maintenance of a wider lumen of the bronchial tree (Barach and Swenson²⁷).

in which expiration is conducted through one of a series of variably constricted orifices, the degree of constriction determining the degree of positive pressure exerted during expiration, so that a pressure of 1 to 4 cm. in expiration during quiet breathing is obtained (Barach and Molomut²⁸). When the volume of ventilation is notably increased, a pressure of 4 cm. through the proper orifice results in a higher expiratory pressure. Recent measurement

FIGURE 1. Intrapleural Pressures and Tidal-Air Volumes in a Dog Breathing through a 5-mm. Orifice.

The tracings on the left were made with the air at atmospheric pressure; those on the right, with the air at 5.5 cm. water pressure.

The use of the mask with a closed-circuit re-breathing apparatus was employed in 1936 before the development of the hood. The apparatus is more cumbersome than the hood, since the removal of heat, carbon dioxide and moisture is necessary and depends on the continuous use of a motor-blower unit. A mask was then devised in which expiration takes place through a rubber tube inserted 3 to 6 cm. under water (Fig. 2).^{*} The length to which the connecting tube is placed under water determines the extent of positive pressure within the mask and therefore the degree of pressure exerted on the respiratory passage and the inner surface of the lungs. Later, a simpler device was used

have shown that during expiration through narrowest orifice an expiratory pressure of 1 to 12 cm. may result. The so-called "meter" with a pressure disk containing variably constricted orifices for expiration is the most convenient apparatus for administering positive pressure, but the degree of pressure actually received actually varies with the volume of ventilation, as described above. A rubber tube extended into a water bottle gives a more accurate expression of the positive pressure, but is more cumbersome. A metered positive-pressure mask may be calibrated by inserting a needle in the mask and connecting it by a rubber tube to a water bottle so that the degree of positive pressure can be accurately determined.

*Manufactured by the Oxygen Equipment Manufacturing Company, Incorporated, New York City.

In the treatment of a case of gas poisoning, both the degree and the duration of positive pressure are determined by a consideration of the factors discussed above. The administration of a positive pressure of 6 cm. may be sufficient to result in disappearance of edema in one to three hours. The pressure may be begun at 3, 4, 5 or 6 cm., depending on the co-operation of the patient. If pulmonary edema disappears during the application of a positive

pulmonary pressure naturally facilitates the inlet of blood into the right auricle. When pressure is applied within the hood, lower pressures should be used, since positive pressure is then exerted on the pulmonary capillaries in both inspiration and expiration. A pressure of 3 cm. of water has been found to be effective in terminating clinical pulmonary edema, although one of 4 to 5 cm. may be used in severe cases. Experience with the hood has

FIGURE 2 Mask with Positive Pressure on Expiration.

pressure of 3 to 6 cm. in a period of several hours, the pressure should be lowered to 2 cm. for one to two hours more. At the end of this time it should be lowered to 1 cm. for one or two hours and then removed. In other cases, if pulmonary edema has cleared, trials should be made of breathing without the mask for a period of five to thirty minutes, and if coughing and edema do not supervene, treatment should be discontinued. In the event that coughing and signs of pulmonary edema recur, the mask should be reapplied and positive pressure used for as long as necessary.

When pressure is applied during the expiratory cycle alone, there is less apt to be any noteworthy interference with the return of blood to the right side of the heart, since blood may enter the lungs during the inspiratory cycle, in which a negative intra-

been limited to cases of clinical pulmonary edema, only masks having been employed by Carlisle for the treatment of gas poisoning.

Although the administration of air containing 40 to 100 per cent of oxygen may be indicated in frank pulmonary edema in which severe arterial anoxia is present, the use of positive pressure with atmospheric air may be all that is required in the prevention of pulmonary edema after gas poisoning. Further studies are necessary to confirm this opinion. If gas poisoning has occurred in combat areas or in localities where oxygen in cylinders is not immediately available, the metered positive-pressure mask may be used by detaching the collecting bag and the rubber tube. Under these circumstances the patient inspires through the inspiratory valve that connects with the outside air; during expiration the

valve closes and the expired air passes outward through a constricted orifice representing a pressure of 2 to 10 cm. of water. Since the permeability of the pulmonary capillaries as well as of the capillaries in the respiratory passage may be altered so as to produce oozing of both serum and mucus, inhalation against positive pressure tends to prevent the onset of the syndrome by neutralizing the internal hydrostatic pressure within the capillaries. Further experience is necessary to determine the range of effectiveness of this method. A three-hour period of breathing against positive pressure is recommended, followed by a gradual lowering of the pressure to that of the atmosphere for one to three hours longer, depending on an estimation of the severity of exposure.

If the metered mask is used with air, the inner surface of the mask should be equipped with an additional emergency inspiratory valve so that a plentiful inlet of air will take place without negative pressure's developing within the mask, even under conditions of severe dyspnea. If mixture of air and oxygen are to be provided, the metered mask, equipped as it is with an injector attached to the regulator, should be employed. With this apparatus oxygen and air are mixed at the regulator and a high flow of the oxygen-enriched air is passed into the collecting bag. The B.L.B. mask²⁹ can be used for the treatment of pulmonary edema if the flow of oxygen used is sufficient to keep the rebreathing bag from completely collapsing during inspiration. If the bag collapses, a negative pressure develops while air is being drawn through the sponge-rubber disks. Another way of using this apparatus without negative pressure's developing in the mask is to fit it so loosely to the face as to do away with the need for the disks.

Since the prolonged administration of 100 per cent oxygen is itself productive of pulmonary edema in animals, and since the specific therapeutic measure is the application of positive pressure, the employment of air containing 40 to 70 per cent of oxygen under positive pressure is recommended rather than that of 100 per cent oxygen. In the prevention of pulmonary edema, inhalation of air under positive pressure is likely to be adequate. In the absence of a mask, the patient should be instructed to exhale through partially closed lips or through a partially closed glottis, as in grunting respiration, thus naturally increasing the intrapulmonary pressure during expiration.

Another procedure of value is the inhalation of the nebulized spray of 1 per cent epinephrine or 1 per cent Neo-Synephrine at intervals of two to three hours. The former is especially valuable in cases of bronchial spasm, and the latter in patients in whom the congestion of the airway is the result of edema. Although the nebulization of these solutions may be accomplished to some extent by hand bulbs, a more effective method is the passage of 5000 cc. of oxygen from a high-pressure cylinder into

a nebulizer containing 0.5 cc. of 1 per cent epinephrine solution or 0.5 to 1.0 cc. of 1 per cent Neo-Synephrine solution (Richards, Barach and Crowell³⁰). These drugs should be administered by inhalation, the end of the nebulizer being held with the mouth, at intervals of two to three hours. The enlargement of the diameter of the bronchial tree either by diminishing bronchial spasm or by vasodilation of the mucous membrane, may be of definite help in decreasing the negative pressure necessary to inhale either air or the therapeutic atmospheric mixture administered.

SUMMARY AND CONCLUSIONS

The inhalation of oxygen and helium-oxygen mixtures under positive pressure has been shown to be of value in the treatment of cases of obstructive dyspnea and acute pulmonary edema commonly seen in the practice of medicine. The only contraindication to positive-pressure respiration described is the presence of shock.

The employment of positive-pressure respiration in cases of industrial gas poisoning indicates that pulmonary edema of the lungs may be prevented and, when it has occurred, tends to respond to the administration of positive pressure in a far more successful manner than under any hitherto suggested procedure.

A pressure of 3 to 6 cm. of water is usually effective in the treatment of pulmonary edema. If signs of edema have cleared, a gradual reduction of pressure over a period of hours is recommended. Prevention of pulmonary edema after exposure to an irritant gas is advocated by inhalation of oxygen against positive pressure for two to three hours and then institution of trial periods of freedom from positive pressure to determine whether or not edema intervenes. Since pulmonary edema may take place as late as twelve hours after exposure, means for providing positive pressure should be at hand in any case in which known contact with a poisonous gas has occurred.

The inhalation of a spray containing 0.5 cc. of 1 per cent epinephrine is helpful in those cases in which bronchial spasm is present, and inhalation of 0.5 to 1.0 cc. of 1 per cent Neo-Synephrine is suggested to increase the lumen of the tracheobronchial tree by vasoconstriction.

In civilian disasters in which phosgene or other toxic gases are liberated, the immediate administration of positive pressure is suggested. Although inhalation of oxygen-enriched air overcomes arterial anoxia, prolongs life, and in some cases saves it, many cases exist in which continued pouring of serum takes place, with impairment of bronchial drainage, secondary infection and bronchopneumonia. Although the sulfonamide drugs may be used to prevent infection, the primary pathological condition is that of a hemorrhagic inflammatory edema, with infection only secondarily produced.

NORMAL AIR ENCEPHALOGRAMS IN PATIENTS WITH CONVULSIVE SEIZURES AND TUMOR OF THE BRAIN*

H. HOUSTON MERRITT, M.D.,† AND CHARLES BRENNER, M.D.‡

BOSTON

WHEN convulsive seizures develop during adult life, the clinician usually considers the possibility that they are a manifestation of some underlying structural lesion in the brain. He therefore studies the patient to exclude the known causes of seizures in adults. Visualization of the ventricles and the subarachnoid spaces by ventriculography or encephalography is one of the tests that are relied on to diagnose or exclude a neoplasm as the cause of the seizures. If the ventricles are found to be of average size and normally placed, the diagnosis of cerebral neoplasm is considered to have been excluded. The fallacy in such an assumption is emphasized by the three case histories given below. These patients had convulsive seizures and each had at least one normal pneumoencephalogram, yet each was eventually proved to have a brain tumor. The duration of seizures before the final diagnosis was established was four, four and a half, and six and three-quarters years, respectively. The first patient had a normal air encephalogram two and a half years after her first convulsion (seventeen months before discovery of the tumor). The second patient had a normal air encephalogram seven months after her first seizure (nearly four years before discovery of the tumor). The third case was the most instructive of all. The patient had two air encephalograms, the first of which, ten months after the first seizure, was interpreted as normal, while the second, ten months later, was considered to show doubtful cortical atrophy on the right, but to be otherwise normal.

CASE REPORTS

CASE 1. H. V., a 38-year-old, married woman, entered the Neurologic Service of the Boston City Hospital on December 1, 1938, because of two generalized convulsions, the first of which occurred 6 weeks before entry. So far as she knew, none of her family had ever had seizures. She herself had had rheumatic fever 15 years previously, and had been deaf in the right ear since an attack of measles in childhood.

Except for a deafness of the middle-ear type on the right there were no abnormal physical findings. The visual fields were normal. Routine blood and urine examinations were normal. The blood nonprotein nitrogen was 26 mg. per 100 cc., and the fasting blood sugar 80 mg. A blood Hinton reaction was negative. Lumbar puncture showed an initial pressure of 60 mm., 2 white cells per cubic millimeter, a total protein of 27 mg. per 100 cc., a gold-sol reaction of 0000000000 and a negative Wassermann reaction. X-ray films of the skull showed evidence of chronic mastoiditis on the right. An electroencephalogram showed no evidence of any focal abnormality.

§Pennybacker, J., and Meadows, S. P. Normal ventriculograms in tumours of cerebral hemispheres. *Lancet* 1:186-190, 1938.

The patient was discharged on $4\frac{1}{2}$ gr. (0.3 gm.) of Dilantin and $1\frac{1}{2}$ gr. (0.1 gm.) of phenobarbital daily and was seen at regular intervals as an office patient. She continued to have seizures of grand-mal type every 1 or 2 months on a daily dose of Dilantin ranging from $4\frac{1}{2}$ to $7\frac{1}{2}$ gr. (0.3 to 0.5 gm. and $1\frac{1}{2}$ gr. of phenobarbital, which was later replaced by 3 gr. (0.2 gm.) of Mebaral. A supravaginal hysterectomy was performed in January, 1941, because of dysmenorrhea. The removed organ was said to be normal. In the following June, the patient is said to have had a right-sided seizure with loss of consciousness. Because her family had also not some personality changes she re-entered the hospital for study in that month.

On examination the patient seemed mentally dull and slow. There was some ataxia of the left leg on a heel-knee test, and the right (*sic*) plantar response was occasional extensor. An air encephalogram was done on June 9, by the lumbar route. There was some subdural air on the left and a possible shift of the ventricular system to the left, which was decided was an artefact due to rotation of the head. The spinal fluid had a normal protein content and colloidal gel reaction.

In the course of the next $1\frac{1}{2}$ years, the patient continued to have monthly seizures despite treatment with Dilantin and Mebaral. She exhibited a marked personality and later intellectual deterioration, which led to institutionalization in February, 1942. In October, she developed a left-sided hemiparesis, headache and vomiting and was readmitted to Boston City Hospital in November.

At that time the diagnosis of brain tumor was obvious. The patient was drowsy and apathetic and had bilateral papilledema and a left-sided hemiparesis, with a positive Babinski sign and a grasp reflex in the left hand. The cerebrospinal-fluid pressure was 305 mm., but the fluid was otherwise normal. An electroencephalogram showed a right frontal focus. On operation 3 days after entry a right-frontal astrocytoma was found that measured 6 cm. in diameter on surface and extended 5 cm. into the brain substance.

CASE 2. G. L., a 27-year-old, married woman, was admitted to the Neurologic Service of the Boston City Hospital on March 18, 1937, because of three convulsive seizures during the preceding month. Each seizure began with numbness and twitching of the left arm, and possibly the left leg, which was soon followed by loss of consciousness lasting 5 to 10 minutes. In one seizure the patient bit her lip. She seemed drowsy after each seizure and complained of numbness of the lips for an hour or two. There was no family history of epilepsy. The patient had had one convulsion in infancy. She was in the 6th month of her first pregnancy at the time of entry.

Physical examination was essentially normal. There was slight puffiness of both ankles, and the tendon reflexes were generally hyperactive. One examiner noted a sustained clonus of the left patella but this was not confirmed by others and there were no pathologic reflexes, weakness or sensory disturbances. The visual fields were normal. The blood pressure was 120/70. The urine was normal except for the slightest possible trace of albumin on one occasion. There was a mild normochromic anemia, with the hemoglobin 12 per cent (Sahli) and the red-cell count 3,540,000. The blood nonprotein nitrogen was 20 mg. per 100 cc. and a blood Hinton reaction was negative. Lumbar puncture showed an initial pressure of 150 mm., no white cells, a total protein of 13 mg. per 100 cc., a gold-sol reaction of 0000000000, color and a negative Wassermann reaction. X-ray films of the skull were normal.

The patient had one seizure while in the hospital. It began with twitching of the left leg, which was soon followed by loss of consciousness, after which the seizure became generalized. The entire seizure lasted 90 seconds. The patient was discharged on $1\frac{1}{2}$ gr. of phenobarbital daily.

had four or five more seizures during pregnancy, of which at least some consisted only of weakness in the left arm and leg and shaking of the left leg for 2 minutes without loss of consciousness.

Seven months after the onset of symptoms, following a normal delivery, the patient entered another Boston hospital for observation. Extensive blood chemistry studies yielded consistently normal results. Lumbar puncture was repeated and the findings again were normal (initial pressure 120 mm. total protein 34 mg. per 100 cc. and other results as before). A ray examination of the skull was said to show thinning of the posterior clinoid processes, but an air encephalogram by the lumbar route showed the ventricles well outlined with no abnormalities.

The patient continued to have six to ten seizures a year at a few days to five months until March 1937. Dilantin was added to the therapy and this she was seizure free for 2½ years. She had another attack of numbness of the body which she could not localize, but there was no loss of consciousness.

A careful neurologic examination at that time was negative except for slight horizontal nystagmus. An electroencephalogram in January 1942 showed a focus of abnormal activity in the right motor area.

The patient tried to take larger doses of anticonvulsant drugs but could not because of dizziness and inco-ordination especially on walking. She continued to have left sided attacks without loss of consciousness, consisting in a feeling of weakness of the affected side, with the occasional addition of twitching of that arm or leg or both. By September she was having about one such seizure a week. Neurologic examination at that time revealed only weakness of the left leg, without abnormal reflexes or sensory disturbances.

Despite the lack of severe or frequent seizures the patient's general condition grew progressively worse and by October 1942 she felt so weak that she stayed in bed most of the time. On November 16, she was operated on and a paramedian craniotomy was removed that measured 14 by 8 cm on its superior surface and ran down the entire depth of the falx to the corpus callosum.

CASE 3. W. R., a 19 year-old, unmarried man, was admitted to the Neurologic Service of the Boston City Hospital in December, 1936 because of convulsive seizures beginning 9 months previously. The maternal grandmother had had epilepsy, and the patient had had three severe injuries at 1, 7 and 12 years all to the left parietal region at least one of which had fractured the skull. At first the seizures consisted of severe pain in the right arm that spread to the right leg, lasting less than a minute followed by numbness, transient aphasia and generalized weakness. Later the seizures were accompanied by tonic movements of the right arm (chiefly extension) and shortly before entry the attacks began to be accompanied by loss of consciousness.

Physical examination on entry was entirely negative as were routine blood and urine examinations, the blood Hinton reaction, x ray films of the skull and an air encephalogram by the lumbar route.

The patient was discharged on 2½ gr. (0.15 gm.) of phenobarbital daily, but his seizures grew more severe and frequent, and in April, 1937, he was started on 4½ gr. (0.3 gm.) of Dilantin daily. This was later increased to 7½ gr. (0.5 gm.) daily. The seizures improved somewhat with this treatment but in September, 1937, he was readmitted to the hospital. This time there was some weakness of the right arm and deafness of the middle ear type on the left. Routine laboratory

examinations were again normal. Another air encephalogram showed normal filling of the lateral ventricles which were normal in size and position. The films were said to show a possible diffuse cortical atrophy on the right (sic).

The patient then went to another Boston hospital where a radical left mastoidectomy was done in November 1937, without relief of symptoms. In February, 1938, a craniotomy was performed there and the left parietal lobe was exposed. The left motor area was found to be atrophic. According to the operative note the pathology was so obvious that no attempt was made to stimulate the cortex. The patient was discharged on 3 to 4½ gr. (0.2 to 0.3 gm.) of phenobarbital daily and continued to have daily seizures.

The patient was readmitted to the Neurologic Service in August 1938. For the first time a right lower facial weakness was noted. Routine studies were normal, but lumbar puncture was not performed.

For the next 4 years the patient spent much of his time either in the Boston City Hospital, the Monson State Hospital or the Boston State Hospital. He exhibited progressive personality deterioration and continued to have frequent seizures despite anticonvulsant therapy. The seizures were usually of the type described above but generalized seizures of grand mal type also occurred and even on occasion seizures localized to the left arm. No changes were noted in the neurologic examination, and the right lower facial weakness persisted unchanged.

In November, 1942 the patient was admitted to the Boston Psychopathic Hospital because of aggressive behavior toward his family, urinary incontinence and failing memory. Physical examination revealed bilateral papilledema of 3 to 4 diopters and right lower facial weakness. Visual acuity was markedly reduced. On December 19, a craniotomy was performed immediately after a ventriculogram and an extremely large fibrillary astrocytoma that had practically replaced the left temporal lobe was removed.

SUMMARY AND CONCLUSIONS

The records are presented of 3 patients with convulsive seizures who had normal air encephalograms, seven, twenty and thirty months, respectively, after their first convulsions but who were subsequently proved to have brain tumors. All three tumors were astrocytomas, one in the left temporal lobe, one in the right motor area and one in the right frontal lobe.

Although brain tumors are among the rarer causes of convulsive seizures, such tumors may cause convulsive seizures without producing any demonstrable distortion of the ventricular system. Cerebral tumors are not apt to produce any change in the ventricular system unless they are large enough to produce focal neurologic signs or increased intracranial pressure, as evidenced by choking of the disks or increased cerebrospinal-fluid pressure on lumbar puncture. If in the absence of these it is decided that an air study is advisable, a negative report should not be accepted as conclusive proof that no tumor is present.

MEDICAL PROGRESS

CARDIOGENIC SHOCK*

NORMAN H. BOYER, M.D.†

BOSTON

IN VIEW of the fact that inadequate cardiac output appears to be the most important direct cause of the clinical picture of shock, it is somewhat singular that in the majority of cases peripheral rather than central circulatory defects are at fault. It is also somewhat singular that wider recognition has not been given to the possibility that shock may result from sudden diminution of cardiac output due to factors inherent in the heart itself. It is generally known that the shock syndrome may arise in a variety of diseases affecting the central circulatory apparatus, but many clinicians feel the necessity of assuming the presence of peripheral vascular collapse in such cases. Even in traumatic shock, the possible importance of heart failure as a sustaining factor has recently received attention,¹ and physiologists have long recognized the importance of cardiac mechanisms in maintaining blood pressure and blood flow.

Clinicians have been accustomed to thinking of all types of shock as having a similar pathogenesis—namely, an insufficient effective circulating blood volume. This point of view has been fostered by the concept that all cases of shock can be attributed to a disproportion between the circulating blood volume and the size of the vascular bed. Atchley² first applied this criterion to both surgical and medical shock, and it has been subscribed to by Blalock³ and Moon.⁴ This definition has the appeal of conciseness and reasonableness, but it leaves out of account the possibility that simple redistribution of blood, with depletion of the arterial side, can occur, and that shock may appear in the absence of any significant reduction of blood volume or increase in the total vascular bed.

That shock can occur in the presence of high venous pressure and adequate filling pressure of the heart is evidenced by the fact that the condition is often seen terminally in patients with chronic congestive heart failure due to hypertension or aortic valvular disease.⁵ Since many clinicians depend on differentiating shock of peripheral origin from shock of central circulatory origin by means of the peripheral venous pressure, it remains to consider whether shock due solely to heart failure can occur in the absence of peripheral venous engorgement, and to inquire into the evidence for and against this possibility.

It is first necessary to review briefly some fundamental facts that must be kept in mind if confusion is to be avoided. It must be readily apparent that the state of the peripheral veins is dependent largely on arterial inflow, and that the reduced arterial flow to the superficial structures in shock results from other things being equal, in collapsed superficial veins. This applies in a somewhat lesser degree to the veins of the neck. Adequate filling of the heart, however, depends on the effective pressure in the auricles—that is, the height of auricular pressure above intrathoracic pressure—and not on pressure in the superficial veins. Right auricular pressure (referred to as atmospheric pressure) in traumatic shock⁶ has been measured and found to be low, but has apparently never been measured in cardiogenic shock. In some forms of the latter, however, the pressure in the femoral vein has been found to be significantly higher than that in the antecubital vein.⁵ Furthermore, the peripheral manifestations of shock are dependent on a diminished output of the left ventricle, the filling pressure of which cannot be gauged by pressure in the right auricle, and even less by pressure in the peripheral veins.

Another important question is whether or not additional blood can be accommodated on the venous side of the circulation without unduly distending any vein or significantly raising the pressure within it. There can be little doubt that in a normal person a venous reservoir exists in the form of unused channels, and that even the channels in use can accommodate more blood without demonstrable effects on the pressure within the veins.⁷ Rapid intravenous infusion of large amounts of fluids can be accomplished in normal persons without only a slight and fleeting rise in venous pressure. Obviously, the amount of additional blood that the venous system can accommodate depends on how well filled the venous system is to begin with, and this is a function of the volume of circulating blood. It has been shown by Gibson and Evans⁸ that the circulating blood volume is regularly increased in congestive heart failure, and that the increase begins with early loss of cardiac reserve and does not depend for its inception on marked congestive failure. It is apparent, therefore, that a cardiac event in a patient with a somewhat increased circulating blood volume may result in a combination of shock and congestive failure, whereas the same event occurring in a patient with a normal blood volume may result in a clinical picture of shock only.

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.
†Assistant professor of medicine, Boston University School of Medicine; visiting physician, Evans Memorial, Massachusetts Memorial Hospitals (on leave of absence).

Support for this reasoning is commonly found in patients with acute myocardial infarction. When this event occurs in a patient previously suffering from congestive failure or loss of cardiac reserve, the striking circulatory alterations are likely to be predominantly manifested by an increase in the signs of congestion, whereas in patients who previously were well the signs of shock are likely to prevail.⁸

Further support for and discussion of the importance of the circulating blood volume, as well as other peripheral mechanisms, in determining the venous pressure in heart failure are offered by Starr, Jeffers and Meade.⁹ These investigators produced severe damage to the right ventricle of dogs, with resultant dilatation and failure of that chamber, without any significant increase in venous pressure. They were led to conclude that the results "give no support to the view that the peripheral venous congestion and the large increment of venous pressure so often associated with cardiac disease in man are caused directly and predominantly by failure of the right ventricle." In other words, heart failure seems to be less important in determining venous pressure than is blood volume or other unknown factors.

One further point in orientation needs to be considered. There are two clinical entities commonly producing the picture of shock that are due to central circulatory faults but not to failure of the heart as a pump. These are the rapid accumulation of fluid in the pericardial sac and massive pulmonary embolism. In both, striking engorgement of the neck veins is usually present and, since this may occur in previously normal patients with presumably normal blood volume, it has been taken to mean that sudden heart failure in previously well patients also results in engorgement of the peripheral veins. This line of reasoning contains an evident fallacy, for in pericardial effusion and in massive pulmonary embolism the pulmonary circuit is largely eliminated as a potential reservoir, and hence the entire amount of redistributed blood must be accommodated in the peripheral circuit instead of in both peripheral and pulmonary circuits, as in sudden failure of the left ventricle. That the pulmonary circuit is a reservoir of no mean magnitude is apparent from the fact that even patients with an increased total circulating blood volume may have no peripheral venous congestion despite a marked increase in pulmonary congestion due to failure of the left ventricle.

Since it is generally conceded that a variety of central circulatory faults may give rise to a combination of shock and congestive failure, this discussion will be mainly concerned with the forms of cardiogenic shock that may, at times, occur with normal or low peripheral venous pressure. If convincing evidence that the clinical picture of shock alone is due solely to cardiac factors can be brought forward, there seems to be no need to invoke peripheral mechanism to explain shock when it occurs in patients with obvious congestive heart failure.

TACHYCARDIA

Wiggers¹⁰ states that increasing the heart rate from 80 to 180 per minute results in a gradual diminution of output per beat with an increasing or steady output per minute, but that at rates above 180 the increasing number of beats per minute is unable to compensate for the diminishing output and, consequently, the total output falls. When the tachycardia is of ventricular origin, the critical rate is somewhat lower because of the abnormal excitation and less efficient contraction of the ventricles. These rates apply to normal hearts, and there is clinical evidence, as well as theoretical reasons, for believing that lower heart rates may significantly reduce cardiac output when there is underlying heart disease. Harrison¹¹ states that the collapse type of cardiac failure may occur with extreme tachycardia — usually over 170 per minute. Wolf¹² studied the effects of tachycardia in 125 patients and had the following to say about shock:

Although a fall in blood pressure was commonly observed during paroxysmal rapid heart action, in only 15 cases did collapse occur. . . . Four patients had normal hearts (1 with hyperthyroidism), 5 had mitral stenosis, 1 had free aortic insufficiency, 2 had angina pectoris, 2 had asymptomatic coronary-artery disease and 1 had recent cardiac infarction. . . . Four patients had congestive failure. . . . The ventricular rate was 200 per minute or more in 7, or almost half the cases, and was less than 150 in only 2.

Three factors appear to be significant in the genesis of vascular collapse: extremely rapid ventricular rates, embolism and aortic valvular disease. . . . When extremely rapid ventricular rates are attained, all other factors may be absent and the heart may be normal. . . . In the presence of aortic valvular disease vascular collapse may occur even though the ventricular rate is significantly under 150 per minute. . . . Occasionally, in elderly patients, vascular collapse may occur with only moderately rapid ventricular rates, even though other contributing factors are not evident.

Sturnick, Riseman and Sagall¹³ studied 21 patients with various types of ectopic tachycardia and found shock in 15. Dyspnea was usually, but not invariably, present, whereas congestive failure occurred only twice. Pulmonary edema was associated with the tachycardia in 4 cases. Only 1 patient in whom shock occurred, a sixty-five-year-old man, was thought to have no underlying heart disease.

Marshall¹⁴ reported a case of circulatory collapse associated with the onset of supraventricular tachycardia at a rate of 215 per minute in a young woman with an essentially normal heart. This occurred post partum, and associated blood loss or other factors may have played a part in the genesis of the vascular collapse.

A few cases of extremely rapid ventricular rates have been reported. These have been collected by Edeiken,¹⁵ who adds a case of his own. This occurred in a patient who was convalescing from acute myocardial infarction that had occurred twenty-four days previously. The onset of supraventricular tachycardia at a rate of 310 per minute resulted in vascular collapse without signs of congestive failure. In discussing other reported cases of extreme tachy-

cardia, Edeiken points out that although collapse or congestive failure may occur it is often surprising how little an occasional patient is incapacitated by ventricular rates as high as 300 or more.

In summary, it appears that tachycardia may produce the clinical picture of shock, in many cases without signs of congestive failure, but that it does not invariably do so. In patients with no underlying heart disease and with no other contributing factors present, shock does not occur at heart rates below 180, and probably but rarely at rates below 200. When underlying heart disease is present, rates well below 150 may produce shock. Since shock itself is commonly accompanied by heart rates of 150 or more, it becomes of some importance, in occasional cases, to determine whether the tachycardia is ectopic and whether underlying heart disease is present.

In view of the correlation of the presence of shock with the onset and offset of tachycardia, and the correlation of observed critical rates with expected critical rates, there appears to be no need to invoke mechanisms other than the cardiac one to explain the presence of diminished cardiac output with resultant shock.

MYOCARDIAL INFARCTION

Infarction of the heart is, of course, the cardiac accident most frequently associated with shock. Often there is clear-cut evidence of both shock and peripheral congestive heart failure, but many cases give clinical evidence of shock alone. Since the clinical findings in cases of shock associated with myocardial infarction are sometimes identical with those in traumatic shock, many clinicians have become accustomed to thinking of both as having a common cause.⁷ It is not to be inferred that this concept is universal, for Harrison¹¹ and many others have long held that shock in myocardial infarction is due to so-called "hypokinetic forward failure." Inasmuch as the therapeutic approach to this grave manifestation of infarction is necessarily guided by a correct understanding of its mechanism, it seems desirable to evaluate the present knowledge concerning it.

At the outset it should be emphasized that, save for neurogenic shock, none of the currently popular theories of traumatic shock can reasonably be applied to shock in myocardial infarction. Certainly, sufficient loss of plasma into the infarct to produce shock cannot well be imagined, and it seems unlikely that liberation of a histaminelike substance sufficient in amount to paralyze the systemic capillaries is of importance. The search for a toxic substance liberated by traumatized or ischemic tissue is periodically revived and has recently been investigated by Green.¹⁶ He was able to produce a shocklike picture in animals by the injection of an extract of skeletal muscle that proved on analysis to be barium adenosine triphosphate. Whether this

substance has anything to do with traumatic shock is still extremely doubtful, but in relation to muscle damage occurring in myocardial infarction it is pertinent to point out that Green found a lethal dose of the crude muscle extract to be roughly equivalent, in terms of fresh muscle, to one fifth the body weight. He also pointed out that the bulk of muscle that must be submitted to traumatic asphyxiation in order to produce severe shock in animals or man is very large. Unless cardiac muscle contains this toxic substance in a content many hundred times that of skeletal muscle, it is apparent that the concept of the liberation of such a substance to account for the shock in myocardial infarction must break down. Furthermore, such explanations leave unaccounted for the fact that the size of the infarct post mortem cannot always satisfactorily correlated with the presence or degree of shock during life.

Since a decrease in circulating blood volume is frequent, though not invariable, finding in traumatic shock, attention has naturally been directed toward this possibility in cases of shock associated with myocardial infarction. Fishberg, Hitzig and Kinney¹⁷ investigated the circulating blood volume in patients with acute myocardial infarction and concluded that the shock was peripheral in origin. Critical analysis of their results, however, shows that significant reduction in blood volume occurred in only 1 case and that actually the average blood volume remained essentially unchanged. In the first edition of his book Fishberg¹⁸ held to the peripheral origin of shock in myocardial infarction, but in a later edition he reversed this opinion.⁸ The absence of a significant reduction in circulating blood volume has been confirmed in patients⁵ and repeatedly in experimental animals.¹⁹⁻²¹

A slight decrease in plasma volume and a slight hemoconcentration have been observed in patients with shock and myocardial infarction.^{5, 22} Stead and Ebert⁵ attributed this to loss of fluid through the pulmonary capillaries subsequent to pulmonary congestion. It is likely that, in some cases, excessive sweating or vomiting is an equally important factor for concentration of the blood proteins indicates loss of water rather than loss of serum or plasma. That the degree of reduction in blood volume is insufficient alone to produce the picture of shock now appears to be demonstrated beyond reasonable doubt.

Measurements of cardiac output in relation to shock in myocardial infarction have been hampered by the fact that the gravity of the illness in human beings has precluded the use of complicated and tiring procedures, and by the fact that shock is not invariably, or even frequently, produced by ligation of the coronary arteries in experimental animals^{19, 20, 23, 24} (a point of some importance that is further discussed below).

Grishman and Master²⁵ measured cardiac output in 5 patients with myocardial infarction by a phle-

ical method involving the determination of the velocity of the pulse wave. None of these patients were in shock, yet their cardiac outputs were significantly diminished. It seems reasonable to suppose that the cardiac output would be even more drastically reduced in the presence of shock. Starr and Wood²⁶ also computed the cardiac output — by means of the ballistocardiograph — in patients with acute myocardial infarction. They, too, found a significant reduction in cardiac output but, strangely enough, severe cases — including those with shock — showed, on the average, less reduction than those with signs of a mild illness. In correlating blood-pressure changes with changes in cardiac output, they state: "This reduction [in blood pressure] did not always run parallel to the diminution of cardiac output, and so was not the result of change in the latter. It should be considered another adaptive mechanism." In view of the suspicion, recognized by Starr himself, that the form and magnitude of the ballistocardiographic waves may be determined by factors other than cardiac output alone, their conclusions cannot be accepted as established. Indeed, it has been shown that, in cases of shock, the ballistocardiogram may give figures for cardiac output that are as high as 75 per cent greater than those obtained by simultaneous determinations made by the direct Fick principle, whereas the agreement in more normal subjects is closer.⁶

Gross, Mendlowitz and Schauer^{19, 20, 22} found that the significant hemodynamic changes occurring in experimental coronary occlusion were a decrease in cardiac output and an increase in circulation time. The blood pressure did not fall significantly, a finding noted by others studying experimental coronary occlusion.²⁴ Mendlowitz, Schauer and Gross²¹ also studied the effects of ligation of the coronary arteries in denervated hearts. In such preparations the decrease in blood pressure was more striking than was that in animals with intact nervous pathways. The authors attributed this to the fact that some of the nervous pathways for compensatory vasoconstriction were interrupted. Since the carotid sinuses were not denervated, their conclusions must be accepted with reservations. Inasmuch as the heart itself was completely denervated, however, their results did indicate that reflexes from the heart were not directly responsible for the decline in cardiac output or blood pressure.

Stead and Ebert⁵ studied 6 patients with acute myocardial infarction and shock. In 3 of these the circulation time was moderately to markedly prolonged, and all showed x-ray evidence of pulmonary congestion. Massie and Miller²⁷ found x-ray evidence of pulmonary congestion in 12 of 16 patients with acute myocardial infarction, although rales were heard in only 7 patients.

In summary, it appears that the shock syndrome in myocardial infarction cannot be attributed to a decrease in venous return, for, in addition to the considerable number of patients who show actual peripheral venous congestion combined with shock, there is evidence, in the form of prolonged circulation time and pulmonary congestion in many cases, that pulmonary venous and left auricular pressures are high. Since the manifestations of shock are dependent on the reduced output of the left ventricle, it is obvious that the left auricular pressure is of greater significance than is the pressure in the peripheral veins. The evidence indicates, therefore, that the venous return to the left ventricle is more than adequate and that the fall in cardiac output with resultant shock cannot be attributed to the mechanisms that are thought to be important in traumatic shock.

(To be concluded)

CASE 30081

PRESENTATION OF CASE

A thirty-nine-year-old housewife entered the hospital because a left thoracotomy wound had failed to heal in the course of fifteen months.

The patient had enjoyed good health until seventeen months before admission, at which time she suffered an attack of pleurisy followed by pneumonia and empyema. She was admitted to a community hospital where, two months after the onset of her illness, a thoracotomy with resection of a portion of the left tenth rib was performed. One of eleven sputum samples examined was reported positive for tubercle bacilli and she was accordingly transferred to a sanatorium, where, during a stay of three months, numerous sputum and gastric examinations failed to reveal tubercle bacilli by smear or by guinea-pig inoculation. During her stay she lost 19 pounds in weight. On one occasion, when her wound was irrigated, she claimed to have expelled some of the irrigating fluid from her mouth. At home, the wound continued to drain intermittently and was associated with a sense of pressure on the left side and back, increasing on urination or defecation. The material discharged varied in color from red and yellow to water-clear; its consistence varied from thick to thin. In the intervals when drainage ceased she developed a cough, which was productive of reddish or yellow foul-tasting sputum. The temperature varied from normal to 104°F., averaging 99. Shaking chills occurred about every six weeks. She had profuse night and day sweats and, for three months prior to admission, dyspnea on exertion. She vomited frequently, especially when trying to work and had lost 50 pounds in the course of her illness. For the week prior to admission, the sense of pressure in the left side developed into a sharp continuous knifelike pain involving the side and back of the left chest and the left flank, radiating down the lateral aspect of the left leg to the ankle. Empirin Compound afforded some relief. She also had burning on urination, but no frequency or hematuria. The menses had been irregular throughout the illness.

Physical examination revealed a pale, weak and markedly emaciated patient in pain. Small tender

*On leave of absence.

nodes were palpable in the left axilla, left groin and both anterior cervical regions. There was diminished expansion of the left chest. A sinus-tract opening was present in the ninth left intercostal space the posterior axillary line. From this point, a tend visible and palpable mass extended downward on the left flank to about the level of the crest of the ilium. The heart sounds were regular and rapid with a crescendo, snapping first sound. The blood pressure was 110 systolic, 55 diastolic. The left leg was held in flexion at the thigh (45°) and knee (90°). Edema of the ankles and feet was present, being greater on the left. Pelvic examination revealed exquisite tenderness in the left vaginal vault, and a mass was palpable in this area on rectal examination. There were numerous external hemorrhoids.

Examination of the blood revealed a red-cell count of 3,500,000, with 60 per cent hemoglobin. The white-cell count was 24,000, with 88 per cent neutrophils. The urine showed adequate concentration with a specific gravity of 1.020, a + test for albumin and 4 or 5 white blood cells per high-power field. The stools were normal. The serum nonprotein nitrogen, sodium and cholesterol were within normal limits.

X-ray examination showed irregular areas of increased density obscuring the lateral chest wall. A defect was seen in the first portion of the left tenth rib, and from this defect a soft-tissue swelling extended down into the left flank. The lumbar spine appeared normal. Lipiodol injected into the first rib revealed a communication with a large cavity apparently reaching almost to the midline, displacing the stomach, and probably the colon, medially and extending downward to a point slightly below the crest of the ilium. The lipiodol moved freely within this cavity, and some of it apparently entered the small intestine. On a film after injection, opaque material was seen in the right upper quadrant. A barium enema revealed ptosis of the entire colon, which appeared normal except for evidence of extrinsic pressure on the descending portion. There was no evidence of communication with the abscess cavity. Thin barium injected into the fistulous opening in the chest wall entered a mass of fingered cavity seen to communicate with the small bowel. Some minutes later barium was seen in the stomach, although no direct communication was observed. Later, after a barium meal, no barium was observed to pass from the stomach into the sinus tract, which appeared to be in close association with the upper lateral wall of the body of the stomach. The barium passed into the duodenum and jejunum, the latter appearing to be several centimeters below the level of the sinus tract. An intravenous pyelogram revealed incomplete outlining of the left renal pelvis, with moderate dilatation and blunting of the calyces. There appeared to be a small pressure defect over the central portion, with incomplete filling of the middle calyces. A gastroscopy revealed a superfi-

gastritis but no positive evidence of a fistulous opening into the stomach. A catheter passed into the chest sinus for a distance of 12 to 15 cm. did not enter the stomach.

The temperature ranged between 97 and 103°F.

The patient received several blood transfusions, one of which was followed by a mild reaction. On the tenth hospital day, the flank abscess was incised and drained. Thick, green, foul-smelling pus was encountered. The abscess cavity was observed to lead up under the diaphragm, toward the fundus of the stomach and splenic flexure and down posteriorly to the tip of the spleen and along the belly of the psoas muscle. Cultures of abscess pus and of material drained from the chest sinus revealed *Staphylococcus aureus*, *Staph. albus*, a nonhemolytic streptococcus, *Bacillus pyocyaneus*, fusiform bacilli and a few colonies of colon bacilli; no fungi grew on Sabouraud's medium. Of several guinea pigs inoculated with this material one was negative, the others dying too soon for a diagnosis to be made.

The wound continued to drain profusely. In spite of numerous transfusions, a stubborn anemia persisted, the red-cell count ranging between 3,000,000 and 3,500,000. The hematocrit varied between 30 and 40 per cent. The white-cell count averaged 17,000, with 71 per cent neutrophils. Several urine examinations revealed large numbers of pus cells. The prothrombin time was persistently prolonged, varying from 25 minutes (normal, 16 minutes) to 37 minutes (normal, 20 minutes). The blood total protein ranged between 4.8 and 6.6 gm. per 100 cc., with an albumin-globulin ratio of 1.0 on one occasion. A bromsulphalein test was negative. A Congo red test showed only 15 per cent dye absorption after one hour.

Because of the stubborn anemia and the evidences of nutritional deficiency the patient was given large doses of vitamins and liver extract parenterally, as well as considerable amounts of adrenocortical extract, in an effort to improve her condition. She was also given large doses of vitamin K (Hykinone).

On the thirty-first hospital day, the flank incision was again explored and the communication of the abscess cavity with the chest sinus was laid open. A necrotic mass presenting itself in the wound was biopsied and was reported as acute and chronic pyelonephritis and perinephritis. On the day following operation a catheterized urine specimen showed gross hematuria, but the urine later contained only 2 or 3 red cells per high-power field, as well as 15 to 20 white cells. Urine culture was positive for colon bacilli on this occasion, as well as for *B. pyocyaneus*, *Staph. albus*, *Clostridium welchii* and fusiform bacilli. An abdominal paracentesis yielded 1700 cc. of straw-colored fluid, which was negative on culture; it had a specific gravity of 1.010 and was negative for acid-fast bacilli and tumor cells.

On the thirty-eighth hospital day, the patient had to be placed on tube feeding because of persistent

vomiting. She continued to vomit, however, and expired two days later.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD H. SWEET: The fact that the thoracotomy wound failed to heal is of interest, since such a wound usually heals unless there is some residual disease.

The attack of pleurisy followed by pneumonia and empyema is another curious thing in this history. So-called "primary pleurisy" is usually caused by the tubercle bacillus. I suppose theoretically tuberculosis exists in the lung and then spreads into the pleural cavity, but ordinarily, tuberculous pneumonia does not follow pleurisy or empyema. The pleurisy follows the pneumonia. So I believe there is something peculiar about the chest situation in this case, and I doubt whether the chest lesion was the primary one. It seems to me that it probably was secondary to something below the diaphragm.

"... numerous sputum and gastric examinations failed to reveal tubercle bacilli by smear or by guinea-pig inoculation." I should like to interpolate that in my opinion the patient did not have tuberculosis because few positive cases are missed in a sanatorium. We have occasionally seen patients in whom supposed acid-fast organisms were found and who were sent to a sanatorium, where no evidence of tuberculosis could be found. Such patients eventually return, and the correct diagnosis of a nontuberculous lesion is made later.

"On one occasion, when the wound was irrigated, she claimed to have expelled some of the irrigating fluid from her mouth." What does that mean? If she had a fistula between the empyema cavity and a bronchus she would not speak of expelling the fluid; she would have coughed and brought it up. Therefore I suggest that the communication must have been below the diaphragm or through the diaphragm into a loop of bowel or into the stomach. Of course one cannot argue too much from the way the record is worded; but if the wording is correct, she did not have a bronchopleural fistula. That raises the question whether she might not have had a lung abscess. Of course, a lung abscess that had perforated, with a resultant empyema, might produce a bronchopleural fistula after drainage of the empyema. But there is no mention of the fact that the pus was foul smelling early in the course of the disease.

"Shaking chills occurred about every six weeks." I do not know of any disease with such periodicity. That does not mean much to me.

Night sweats may go with tuberculosis of the lung, but they may accompany any type of sepsis. She had a right to have the dyspnea on exertion. Furthermore, she appeared to have been sick enough to lose 50 pounds in weight, and I do not believe to assume that she had tuberculosis.

This is probably not a prime cause she had no hematuria

enough sepsis to account for the tender lymph nodes. The tender mass and the pain make one think that she had an abscess in the flank, and as the case develops, the whole question centers on the abscess in that region. She has psoas spasm, which indicates that it was a deep abscess extending along the course of the psoas muscle. Pelvic examination confirmed that impression because it revealed "exquisite tenderness in the left vaginal vault." In other words this abscess had burrowed its way down through the flank and into the pelvis, which is not at all uncommon. The diagnosis, I think, will be greatly influenced by the x-ray films.

There is reasonably good evidence, both clinically and by x-ray, of perinephric abscess, or possibly subphrenic abscess. I am inclined to think it was the latter.

"On a film after injection, opaque material was seen in the right upper quadrant." It does not say whether that was in a hollow viscus or in the peritoneal cavity. If it was in the peritoneal cavity, we must be dealing with a subdiaphragmatic abscess.

"Later, after a barium meal, no barium was observed to pass from the stomach into the sinus tract, which appeared to be in close association with the upper lateral wall of the body of the stomach." That is exactly where it would be if it were a subdiaphragmatic abscess. It appears that we have evidence of a fistula communicating with the jejunum but not with the stomach or with the colon.

There is no mention of a tumor or of an ulcer on gastroscopic examination.

DR. LAURENCE L. ROBBINS: In the chest films there appears to be something in the region of the left costophrenic angle that I think could be all pleural. There is nothing definite within the lung. These films show that the sinus tract passes anteriorly and divides into many small branches. I assume that this is the material that went into the small bowel, and on one of the large films we can see that it has appeared in the stomach. The one thing that is impressive is that there is no evidence of a visible outline of the left kidney, and the psoas shadow is obliterated. The stomach, except for displacement, is not abnormal.

DR. SWEET: The sinus leads into the abdomen, however.

DR. ROBBINS: It goes a considerable distance farther forward than one would expect to find the kidney. It extends to a plane anterior to the spine.

DR. SWEET: Dr. Robbins is anticipating me. I was going to say that this could not have been a perinephric abscess.

It is rather interesting to speculate why adrenocortical extract was given. Because of the fistulous tract I wondered about diarrhea, but there is no mention of it. She had some disease that depleted her.

DR. FRANCIS D. MOORE: The patient did not have diarrhea.

DR. SWEET: This patient, with months of observation under medical care, had several attempts made to prove or disprove the diagnosis of tuberculosis. I believe it is reasonable to exclude such a diagnosis. As I have said, the sanatoriums do not miss that diagnosis very often, and one guinea-pig inoculation in this hospital, after the lapse of a proper length of time, showed no evidence of it. Therefore we must come down to a consideration of the etiology of a large subdiaphragmatic or perhaps perinephric abscess.

Perforation of a perinephric abscess into the abdominal cavity is a most unusual occurrence. I do not recall seeing it. Dr. Colby, who has seen many more perinephric abscesses than I have, tells me that he has seen only one that ruptured into the abdomen. We must always keep the two things entirely separate. Therefore, if my reasoning so far is correct, we are dealing with an abscess in the left upper quadrant of the abdomen, a subdiaphragmatic abscess that has done a number of things—namely, perforated through the diaphragm to cause empyema, extended into the pelvis and produced pyelonephritis. I have perhaps excluded the lung and pleural cavity as the source of all this mischief a little too rapidly, but there is no mention of anything that makes me think she had disease in the lung. The x-ray films do not show any residuum of disease in the lung, and the story suggests that she had something going through the diaphragm, and as we see later, she had a fistula. An empyema rarely perforates into the peritoneal cavity; on the other hand, a subdiaphragmatic abscess frequently perforates into the pleural cavity. Thus, the current is the other way. With these apologies, I shall exclude the chest as the source of the disease.

If there was a subphrenic abscess, either intraperitoneal or abdominal, where did it come from? A subphrenic abscess always arises from some septic focus within the abdomen. The commonest cause is a perforated viscus, such as a ruptured gall bladder, appendix or diverticulum, or through a malignant tumor in a hollow viscus. Occasionally a liver abscess perforates and causes a subphrenic accumulation of pus, but that is unusual. Then there is the occasional case in which a picture like this can be explained entirely by acute pancreatitis. Some patients with necrosis of the pancreas develop large accumulations of pus, usually in the left part of the upper abdomen, which ulcerate into the viscera, perforate the diaphragm or gravitate down along the psoas muscle or even into the pelvis. In such cases, we sometimes drain the pancreatitis through the inguinal region because the abscess has presented as a bubo in the groin, having gone all the way down by the retroperitoneal route.

There is one other condition that I have not mentioned because it did not seem to fit in very well. Could the trouble have started from an infection in the spine—an osteomyelitis? When I originally

thought of tuberculosis I wondered if it might have been a tuberculous lesion starting in the spine. The x-ray films do not suggest a spinal lesion, and the patient did not behave like one with osteomyelitis of the spine.

I should conclude my discussion by deciding whether this subdiaphragmatic abscess arose from a ruptured viscus or from an acute pancreatitis, but I cannot say which it was.

DR. CASTLEMAN: The field is still wide open.

DR. FLETCHER H. COLBY: The possibility of perinephric abscess is naturally good. My experi-

whole region, including the kidney. Later on, as we got the x-ray films, it seemed that the viscus entered was not the splenic flexure but either the stomach or the small bowel. We continued working on that assumption—accidental perforation through the low thoracotomy site, which had allowed sepsis to be introduced into the abdomen from the gastrointestinal tract.

The patient was given adrenocortical extract because, along with the chronic pyogenic infection, she had evidence of adrenal insufficiency. The blood sodium was 120 millicequiv. per liter, and the 17-

FIGURE 1. *Actinomycotic Clumps in an Abscess of the Liver.*

ence with a perinephric abscess that involves the peritoneal cavity is rare. In the only case that I can remember, the patient died very quickly. Whether it can involve the intraperitoneal contents without causing peritonitis, such as this individual had, I do not know.

DR. MOORE: When the patient came in on the surgical service she presented the enigma that Dr. Sweet has described; she had supradiaphragmatic and subdiaphragmatic sepsis, and the problems were how it got from one place to the other, and what was the origin. Our reasoning was guided by one fact that is not stressed in the abstract of the history. The original thoracotomy wound was at the level of the tenth rib in the midaxilla; this was too low for the drainage of an empyema, and was so low that one could with great ease penetrate through the diaphragm and perforate a subdiaphragmatic viscus. We thought that this accident had occurred, possibly with perforation of the splenic flexure, and that this gastrointestinal sepsis had swamped the

ketosteroids were low. We gave the extract in an effort to restore this endocrine imbalance.

CLINICAL DIAGNOSES

Subdiaphragmatic abscess, probably originating from perforation of intestine.
Pylonephritis.

DR. SWEET'S DIAGNOSIS

Subdiaphragmatic abscess, originating from perforated viscus or acute pancreatitis.

ANATOMICAL DIAGNOSES

Actinomycosis of left retroperitoneal and retropleural spaces, left kidney and liver.
Perforation of splenic flexure of colon.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this patient showed what was to be expected—a large abscess in the left retropleural and retroperitoneal regions

extending from about the level of the fourth rib through the diaphragm down to the level of the head of the femur. It did communicate with the splenic flexure, and not with the small bowel. There was a definite fistulous tract between the abscess and the splenic flexure. The kidney on that side was practically destroyed by this abscess, and we were unable to find the left adrenal gland. We also noticed that the liver was full of abscesses of varying sizes, which contained yellowish-green material. We made a diagnosis of abscess (type undetermined), with abscesses of the liver, and thought that the patient had a terminal septicemia.

Microscopic examination of the wall of the abscess, as well as of the abscesses within the liver, showed large numbers of actinomycetes. Hence, there was definite actinomycotic infection of the kidney, retroperitoneal space and the lower part of the left pleural cavity. The left lower lobe was completely collapsed, and we were unable to find any evidence of infection within the lung itself. Until Dr. Moore just said what he did about the rib resection, I was at a loss to explain how the actinomycotic infection arose. If it had arisen from the lung, as it often does, it would seem a little far fetched to believe that the infection within the lung disappeared and that the infection below the diaphragm continued. Also, a primary actinomycotic infection of the kidney is extremely rare; I think that it has been reported but it is ordinarily a secondary infection. I now believe that the perforation of the splenic flexure at the time of the rib resection released the organisms, which we know are often present in the normal colon. After the infection was well established, the portal vein was invaded by the organisms and a diffuse hepatic infection resulted.

DR. MOORE: Have you any explanation why the biopsy showed no actinomycetes?

DR. CASTLEMAN: We reviewed this slide after the autopsy and still could find no evidence of actinomycotic infection.

DR. MOORE: I might also mention that Dr. Cora Owen, of the Surgical Bacteriological Laboratory, who is interested in the study of actinomycoses, was unable to culture them. There was a large quantity of material to work with, and it was planted on all kinds of mediums at varying oxygen tensions, but no organism grew out.

DR. CASTLEMAN: The liver abscesses were full of actinomycotic clumps (Fig. 1). It is the best case that we have seen since the days of Dr. J. Homer Wright.

CASE 30082

PRESENTATION OF CASE

A sixty-five-year-old man, a retired bank clerk, was admitted to the hospital with anorexia and epigastric pain.

About three months before admission the patient began to experience anorexia, associated with gnawing pain in the epigastrium and region of the umbilicus. The pain was worse early in the morning and from a half to two hours after meals, but was not relieved by food. It was associated with deep pain in the back, at about the level of the seventh to the ninth dorsal vertebra, and with increasing weakness and malaise. For several weeks prior to admission he had complained of frequent attacks of nausea after meals, aggravated by the ingestion of greasy foods. He also stated that his bowel movements, which had occurred regularly twice daily, altered to once a day. Twelve days before entrance into the hospital his bowel movements ceased entirely for a period of six days, during which time only flatus was passed, but a dose of castor oil brought relief. Two days before admission, after taking a drink of whisky, he had an episode of bilious vomiting. Over a period of nine months the patient had lost 40 pounds of weight, half of this in the two or three months prior to admission. He had had an early morning cough associated with a small amount of expectoration for as long as he could remember, but he first noted wheezing about six months before entry. The wheezing was most noticeable when he was lying down, and diminished when he sat up. In the two months before admission, he had also noticed that he could walk only short distances without becoming short of breath, and in addition, his ankles were somewhat swollen. No orthopnea was present.

At the age of ten, the patient had rheumatic fever and was confined to bed for three weeks. At about the age of twenty-five, he had a chancre of the penis associated with a positive Wassermann test, for which he was treated over a period of two years. At about the same time he had gonorrhea. Twenty years before admission he had an attack of pain in the right upper quadrant, associated with nausea and vomiting, and following this a cholecystectomy and appendectomy were performed. Five years before admission he had an attack of abdominal pain that was diagnosed as being due to intestinal obstruction. He was admitted to a hospital but was treated nonsurgically. The patient was a moderate smoker, but drank heavily, consuming about a pint of whisky daily until he ceased working several years before admission. Since that time he usually drank seven or eight glasses of beer daily. During the year prior to admission he developed pain in the shoulders and hips, which was aggravated by cold weather and caused some difficulty in walking. His mother had died of cancer of the liver.

Physical examination revealed a weak, poorly nourished man. The skin was rough to touch, and there was exfoliation over the shins. Circumscribed areas of pigmentation and exfoliation were present in the axillary and inguinal regions. Numerous telangiectases were present on the face. On the

buccal mucosa were numerous soft, blue, vascular nodules, some of which were lobulated. The scleras appeared icteric. The lungs revealed diffuse inspiratory bronchial rhonchi, and an area of dullness to percussion was present about a handbreadth below the right axilla, extending posteriorly and unassociated with changes in breath sounds. In the epigastrium a nodular mass could be felt extending seven fingerbreadths below the xiphoid process and to the left midclavicular line; the edge was blunted and tender. In the right midclavicular line the liver edge was palpable two and a half fingerbreadths below the costal margin. There was some tenderness, and a suggestion of a mass, in the left upper quadrant. The extremities revealed a fine muscular tremor, tortuous brachial arteries, cyanotic and brittle nails, and redness and mottling of the palms. The knee jerks were active, and the Babinski sign was positive bilaterally.

The blood pressure was 150 systolic, 110 diastolic. The temperature was 98°F., the pulse 88, and the respirations 20.

Examination of the blood showed a red-cell count of 3,920,000, with a hemoglobin of 15 gm. The white-cell count was 8000, with 78 per cent neutrophils. The urine was negative. The stools were loose, brown and guaiac negative. The van den Bergh was 1.6 mg. direct and 2.5 mg. indirect. The blood phosphatase was 10.5 Bodansky units per 100 cc. The blood nonprotein nitrogen, the carbon dioxide combining power and the chloride were within normal limits. The blood protein was 6.8 gm. per 100 cc., with an albumin-globulin ratio of 0.8. The cholesterol was 225 mg. per 100 cc. A cephalin flocculation test was ++ after twenty-four and forty-eight hours. A blood Hinton test was negative.

A gastrointestinal series showed displacement of the stomach to the left and anteriorly by a mass in the region of the liver, and a pressure defect was present on the lesser curvature. A barium enema revealed several diverticula in the proximal portion of the sigmoid, but was not otherwise unusual. A roentgenogram of the chest showed an area of increased density in the left lower chest, blunting of the left costophrenic angle and a prominent left hilus.

The patient was given a high vitamin diet and intravenous fluids but failed to respond; he gradually became stuporous and comatose and expired quietly on the twentieth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. FRIEDRICH W. KLEMPERER: This patient's chief complaint points toward involvement of the digestive system, and physical as well as x-ray examination demonstrated a mass that in all probability was the left lobe of the liver. There are a number of possibilities to explain the enlargement of the liver in this patient. He had had syphilis twenty-five years before admission and he could

have had a syphilitic cirrhosis. We know, however, that he had immediate and apparently adequate treatment and his Hinton test was negative. Neither of these rules out late syphilis but taken together, as well as the fact that involvement of the liver in late syphilis is quite rare, they make this diagnosis highly improbable.

The patient was also an alcoholic, and portal cirrhosis of the liver is therefore a good possibility. Several statements in the record, however, are against cirrhosis as the chief source of his trouble. These are the extremely rapid progression of the symptoms, the emaciation and presumably the increase in the size of the tumor, the absence of ascites or evidence of collateral circulation and the absence of splenomegaly. All these facts, however, could be easily explained if the patient had developed a hepatoma on the basis of an early cirrhosis. This must be weighed against the probability of metastatic malignancy to the liver.

What is the evidence we have for a primary lesion elsewhere? The patient had had an attack of so-called "intestinal obstruction" five years before admission. The lack of progression and medical cure definitely rule out the presence of cancer of the bowel at that time. We know that he had diverticulosis at the time of admission, and his previous attack of abdominal pain can logically be explained as having been due to diverticulitis. The recent change in bowel habits seems unlike that usually seen in obstruction due to malignancy and can easily be explained as secondary to the liver disease. The stools were guaiac negative. I see no reason why we should doubt the x-ray evidence that there was no lesion in the large bowel. Similarly we have no evidence that leads us to place the lesion higher in the intestinal tract. Primary carcinoma of the pancreas must always be thought of because it so easily escapes clinical detection. This is an appealing diagnosis because it would explain the character and distribution of the patient's pain near the umbilicus and in the back. Such a lesion would have to have been located in or near the tail of the pancreas, because carcinoma of the head would have led to progressive and severe jaundice. Although primary carcinoma of the pancreas is a distinct possibility, I am going to discard it in favor of a primary lesion in the lungs.

It should be remembered that nine months before admission — that is, six months before the onset of abdominal symptoms — he began to lose weight. Definite respiratory symptoms also preceded the abdominal symptoms by three months. The patient complained of wheezing respirations and dyspnea. These symptoms, particularly in the absence of orthopnea, are highly characteristic of lung tumor. They are most frequently seen in bronchiogenic carcinoma but can also occur in metastatic malignancy. For two reasons I am inclined to believe that the pulmonary lesion was primary rather than

metastatic from a primary lesion in the liver or pancreas. The first is the fact that the pulmonary symptoms preceded the abdominal ones by several months, and the second, that Dr. Robbins tells me that the x-ray changes in the chest are unlike those seen in metastatic malignancy. The age of the patient and the clinical course seem consistent with the diagnosis of bronchiogenic carcinoma with metastases to the liver. I see no evidence in the record to make one consider seriously the possibility of lymphoma or even sarcoma.

There are several points in the record that require comment. The patient had skin lesions. I interpret these as having been due to nicotinic acid deficiency. The telangiectases do not seem to bear any relation to the patient's illness. Their description does not indicate that they were the spider angiomas sometimes seen in cirrhosis of the liver. The patient had joint pain. The multiplicity and symmetry of involvement are against metastatic disease. There are not enough data to differentiate degenerative joint disease and rheumatoid arthritis. The latter seems somewhat more likely in view of the joint disease that the patient had during childhood, then diagnosed as rheumatic fever. The laboratory data indicate some parenchymal involvement of the liver. This may mean that the patient had a cirrhosis of the liver in addition to metastatic disease, but it is known that extensive malignancy can produce these changes. The immediate cause of death was probably general malnutrition but possibly liver failure.

CLINICAL DIAGNOSIS

Metastatic carcinoma of liver (?source).

DR. KLEMPERER'S DIAGNOSIS

Bronchiogenic carcinoma, with metastases to liver.

ANATOMICAL DIAGNOSIS

Oat-cell carcinoma of lung, with metastases to regional lymph nodes, liver, pericardium, right adrenal gland and rib.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The post-mortem examination disclosed a primary tumor in the lower or lingula branch of the left upper-lobe bronchus, with almost complete obstruction. The tumor involved about 4 cm. of the bronchus and had extended into the surrounding parenchyma. The carinal lymph nodes were involved and were matted together to form a 6-cm. mass. The lung distal to the tumor showed secondary bronchiectasis. The liver weighed 3000 gm., and about three fourths of it was replaced by metastatic cancer. Other metastases were present in the parietal pericardium, the right adrenal gland and one of the ribs. Microscopically the carcinoma is of the oat-cell type. This is the type that is usually located near the hilus and grows very rapidly.

We found no evidence of syphilis.

A MARCH OF MERCY

As Red Cross Month comes around, the Nation is reminded once more of the American Red Cross and its stupendous task of relieving human suffering. The organization is national only in name, for its fighting fronts have been extended to every corner of the globe.

The immediate need is for blood donors and nurses. During 1944 the Red Cross must supply some 5,000,000 blood donations for military and civilian needs, and each month 2500 nurses must be received for the Army and Navy. In addition the large corps of field directors, hospital workers and other trained personnel must be kept at fighting strength, and where necessary increased. An im-

portant part of the war work is the preservation of morale in the armed forces by maintaining contacts between soldiers and sailors and their families, especially when domestic troubles arise. It goes without saying that, as ever, the American Red Cross must be ready to cope with disasters and epidemics at home, as well as with the endless needs of a nation at war.

All the activities of this vast organization are financed by voluntary gifts and contributions. During March, designated by President Roosevelt as Red Cross Month — in both senses a March of Mercy — the American Red Cross must raise a war fund of unprecedented size to meet unprecedented needs. More than ever, a generous answer to its appeal will be a gesture of patriotism and a sign of love for mankind.

PENICILLIN IN WOUNDS

ALTHOUGH only a small number of physicians in this country have had an opportunity to use penicillin, it is now fairly well established that this agent is highly effective in the treatment of many types of bacterial infection. It has already proved to be a lifesaving measure, surpassing the sulfonamide drugs in effectiveness under certain conditions. This has been particularly true in certain cases of staphylococcal septicemia and of meningitis. It is also highly effective in the treatment of infections with strains of gonococcus and pneumococcus that are resistant to sulfonamide therapy, and it may eventually prove to be the most effective agent in the treatment of syphilis and perhaps of other infectious diseases. The results of studies of the use of penicillin in surgical conditions in the past indicate that large doses are needed in the successful treatment of well-established wound infections, frequent doses of the drug being given parenterally and locally for long periods. In view of the limited supply now available, only a small percentage of established wound infections can receive the benefits of treatment with this agent.

The question naturally arises whether the early use of penicillin locally in fresh wounds wards off serious infections. Should it be possible thus to prevent infection in fresh wounds of soft tissue and

in compound fractures, obviously a large number of patients would be spared prolonged and severe illness and many limbs and even lives would thus be saved. Furthermore, this might readily be accomplished with a relatively small amount of penicillin and could, therefore, be made soon available for use in large numbers of battle wounds in the present conflict.

To investigate this aspect of the management of wounds, two eminent British investigators, Professor H. W. Florey, who has been intimately associated with the developments in penicillin therapy, and Brigadier Hugh Cairns, a leading surgeon, set out to make an intensive but brief study of the treatment of wound sepsis in North Africa. They had the collaboration of many medical officers and investigators. A detailed preliminary report of their findings was made to the British War Office and to Medical Research Council, and an abstract of this report has been published.¹ An additional study in Britain of the value of penicillin in infected burns and surface wounds is reported in the same issue of the *Lancet* by Flight Lieutenant D. C. Bodenham.²

In the investigations in the Mediterranean area local applications were made in four forms. The first was a solution of the calcium salt in distilled water or saline (250 to 500 units per cubic centimeter), and the second, a cream with lanette wax (250 units per gram). The latter holds penicillin in contact with tissues longer than is possible with a water solution and is itself soluble in water. The third form was crude, dried calcium penicillin applied directly to the infected surface, the penicillin dissolving in the fluid present. This method was thought to be unnecessarily wasteful because the powder is difficult to spread thinly over a large wound; furthermore, the powder, as such, is irritating when used locally. Finally, the powder, diluted with a sulfonamide, was insufflated on the infected area with a blower — sulfanilamide was used by Florey and Cairns, and sulfathiazole by Bodenham. The mixture contained 500 to 5000 units of penicillin per gram. In many cases it was necessary to supplement local treatment with parenteral therapy in large amounts.

A small number of chronic septic wounds of three to four months' standing were treated at Algiers.

The results in these cases were not encouraging, and it was concluded that treatment of long-standing septic compound fractures would require large amounts of penicillin, which might be more profitably used in more recent wounds.

Early closure of soft-tissue wounds was carried out in 171 cases by ten surgeons at five general hospitals at Tripoli and Soussé. Most of these wounds were three to twelve days old when closed; they were usually infected, and some were actually purulent. As experience and confidence grew, it was found possible to close almost all wounds except those in which the missile had produced gross destruction of skin. The medical officers who carried out the treatment were most enthusiastic about the results of closure of recent fresh wounds, and one of them remarked that with penicillin the obstacle of infection had been practically overcome.

In the treatment of recent compound fractures the aim was to prevent chronic infection and to convert them as soon as possible into closed fractures by suturing the wound. The cases available had been temporarily immobilized in the forward area and were five to fourteen days old on arrival at the base hospital. In this group, intramuscular injections or injections by continuous drip of penicillin were used, up to a total of 500,000 units, in addition to the local therapy. The wounds were completely sutured, except for a few in which this was mechanically impossible. In summing up the results obtained in recent fractures it was thought that too much had been attempted in the way of wound closure. Thus, in a comminuted fracture, it seemed better to leave potential drainage to the exterior for the first week or ten days. It was also thought that the dosage in the compound fractures of the tibia and femur was too small — in other words, that total of 700,000 to 1,000,000 units should be given over a period of seven to ten days, although this might prove unnecessary in patients who had received penicillin in the forward area.

Only a small number of cases of gas gangrene were treated. Although there was some evidence for a favorable effect, the final results were not encouraging: toxemia was not counteracted, and it was thought that fulminating cases could not be saved by penicillin alone. On the other hand, it was

stated that penicillin might be expected to play an important role in prevention.

The study of the use of penicillin in head wounds was chiefly limited to cases of penetrating brain injury of three to twelve days' duration. Almost all of them were infected with gram-positive pyogenic organisms, and about half were frankly suppurating. These wounds were excised, cleaned and closed, and injections of a solution of calcium penicillin were given every twelve hours for three days through a stab wound into the brain cavity. The average total dosage was 15,000 units. The penicillin-sulfanilamide powder was applied to the wounds during dressings and occasionally during operations, and a small number of patients with compound fractures in other parts of the body also received intramuscular doses of penicillin. The results in this group were encouraging. Gram-positive cocci usually disappeared from the wounds within forty-eight hours. The observers state that penicillin deserves an extensive trial in brain wounds for which definitive treatment cannot be given before seventy-two hours. For earlier cases they believe that the sulfonamides are adequately effective. Nonpenetrating wounds were successfully closed and treated with penicillin solution through tubes for three to five days, a total dose of only 3000 units being used. In scalp wounds not associated with fractures, healing by first intention was secured with a single application of 1 to 3 gm. of penicillin-sulfanilamide powder after excision.

Penicillin applications were also tried on a few burns that had remained persistently infected by hemolytic streptococci in spite of sulfathiazole by mouth and sulfadiazine locally. The response of these burns to extremely small doses of penicillin-sulfanilamide powder was uniformly rapid, and free grafts took satisfactorily in spite of the presence of pus containing gram-negative organisms. About 20,000 units was adequate in such cases.

No attempts were made by the British investigators to compare the results of penicillin therapy with those of other forms of treatment. Obviously this would have required extensive and carefully controlled studies and would have been futile unless it had been found that the penicillin itself was effective in the various conditions in which it was

used. They therefore confined themselves to ascertaining the range of usefulness of penicillin in the treatment of wounds, and the best methods of applying this form of therapy. The present results merely suggest that penicillin treatment is feasible and useful under certain field conditions. No claims are made that it is better than any other form of therapy. How useful it is and how it will compare with the results obtained with sulfonamides and other forms of therapy remain for further study.

The divergent results reported from the use of sulfonamides in the treatment of wounds illustrate well how difficult such a problem can be. Early reports of sulfonamide therapy were most enthusiastic, whereas in later ones the optimism was considerably tempered. This is illustrated in Meleney's recent report of the Subcommittee on Surgical Infections of the National Research Council.³ The members of this committee concluded from their extensive studies that sulfonamides minimize the general spread of infection in wounds and cut down the incidence of septicemia and death. They had no evidence, however, that the incidence of local infections was lessened by the sulfonamides as they have been employed. They state that, if the incidence of local infection in war wounds and burns is to be decreased, some other form of sulfonamide or some other bacteriostatic agent must be found that is effective against the contaminating organisms in the presence of damaged tissue. Penicillin is such an agent, and the studies of Florey and Cairns indicate that it may be useful by itself or as a supplement to the sulfonamides.

MEDICAL EPONYM

STEVENS-JOHNSON SYNDROME

"A New Eruptive Fever Associated with Stomatitis and Ophthalmia" was described by Albert M. Stevens (b. 1884) and Frank C. Johnson (1894-1934) of Columbia University and Bellevue Hospital in the *American Journal of Diseases of Children* (24: 526-533, 1922). A portion of the article follows:

During a period of three months we had the opportunity of observing two cases of an extraordinary, generalized

eruption with continued fever, inflamed buccal mucosa and severe purulent conjunctivitis. . . .

. . . . No diagnosis could be made to correspond with the symptoms and course of the eruption in these two cases and no description was found of a skin condition in any degree comparable.

. . . . Here is a syndrome of dramatic onset, with fever, conjunctivitis and cutaneous eruption. The child is prostrated, the mouth and tongue are inflamed and raw, the eyelids are swollen and pus streams from the eyes. There is a course of three or more weeks of high fever, with leukopenia. The eruption, unlike any hitherto described, comes out progressively, for two weeks or more, matures and resolves in horny crusts, in the order of its appearance. The temperature falls with this resolution of the skin lesions. This syndrome suggests strongly an infectious disease of unknown etiology. We believe that this condition deserves to be considered a definite clinical entity.

WAR ACTIVITIES

INDUSTRIAL HYGIENE

CARBON TETRACHLORIDE POISONING IN PARACHUTE FACTORY

The cause of illness among 135 employees in a Kentucky plant manufacturing parachutes was traced to carbon tetrachloride used for cleaning soiled spots on the chutes, according to an investigation by the Kentucky Division of Industrial Hygiene. The outbreak of illness occurred during a period of ten days and was manifested by abdominal cramping, nausea and vomiting. Some workers complained of "bloating and difficulty in breathing." Many employees were acutely ill and unable to continue work. The illness lasted from two to five days in the average case, although a number of workers continued to feel bad after resuming work.

The possibilities of food poisoning were ruled out by questioning of ill employees about food consumed in the forty-eight hours preceding onset of illness. The absence of fever and diarrhea indicated that the disease was not an intestinal disorder of bacillary origin. On further study, the nursing records revealed that a great many employees complained of frequent or even constant headaches, and complaints of gastric distress had been especially numerous for several weeks. The fact that the incidence of the disease was restricted to workers on the first shift, and to those whose work placed them in the same environment, pointed to some special factor such as a toxic chemical. A check of the records revealed that out of 137 sick employees, 135 had been engaged in sewing and cleaning the nylon used in manufacture.

It was found that more cleaning of the chutes had been done in recent weeks and that at times pure carbon tetrachloride had been used in place of the usual solvent. The solvent was kept in open containers, and an estimated 4 gallons were used daily. With the beginning of the cold weather season five or six weeks previously, ventilation was provided only by opening windows along the skylight, the side windows being closed. Since the fumes of carbon tetrachloride gas have a density 5.3 times that of air, they could only be removed by vents at the floor level. It was significant that the first noted symptoms were coincidental with the beginning of heating, and the consequent reduction of ventilation in an effort to conserve fuel.

The recommendation made for substitution of some other solvent was quickly adopted. The use of carbon tetrachloride was immediately ordered discontinued, and cleaning of parachutes is now being done with soap and water. — Reprinted from *Industrial Hygiene News Letter* (January, 1944).

MISCELLANY

HEMORRHAGE IN PULMONARY TUBERCULOSIS

In the life of any individual the sudden spitting of blood is a dramatic and fear-stirring event. Usually it is brought to the attention of the physician so promptly that an accurate and rapid diagnosis is possible. Self-neglect, however, is encountered on the part of some patients. Errors in diagnosis, too, are not unheard-of happenings. Thus there is every good reason why such an alarming symptom as hemoptysis must be viewed with concern by the doctor until the cause has been established and the proper emergency care and long-term treatment provided. In this regard, the following abstract of a recent article (Minor, G. R. Hemorrhage in pulmonary tuberculosis. *Am. Rev. Tuberc.* 48:109-114, 1943) is of interest.

Pulmonary hemorrhage is one of the most distressing phenomena encountered in medical practice. The patient is gravely alarmed and the physician is confronted by bleeding that comes from a point deep within a delicate organ enclosed in a rigid framework. To combat the bleeding there may be only slowly or doubtfully effective physiologic mechanisms.

Psychologic effects to one side, hemoptysis generally is indicative of serious pulmonary disease. It is recognized that unexplained blood-spitting must be considered due to tuberculosis until proved otherwise. Occasional causes, however, include such nontuberculous diseases as bronchiectasis, bronchogenic carcinoma, lung abscess, rheumatic

heart disease and various minor nose and throat affections. People apparently in good health and presenting negative physical signs and few or equivocal roentgenologic findings represent especially puzzling problems when they report having coughed up blood. In all cases it is essential that we exhaust every means at our disposal of tracking down the reason for obscure lung hemorrhage.

The causes of hemoptysis are still not clearly understood. Blame has been laid on deficiency in one of the factors concerned in blood coagulation, on tonic, nervous or endocrine factors, on erosion of a vessel wall by a tuberculous process, on rupture of a small aneurysm within a cavity. Although the most serious hemorrhages occur in old, fibro-ulcerative tuberculosis, small or moderate hemoptyses may be seen in early disease, sometimes as the first recognizable symptom. Softening of a lesion or progression of an established process may be accompanied by hemorrhage.

Among 1000 patients consecutively discharged from the Blue Ridge Sanatorium, Charlottesville, Virginia, only those were included in this study who gave a clear-cut history of spitting up 1 dram or more of blood, or who suffered a hemorrhage during their stay in the institution. "Streaking," "streaked sputum" and indefinite history of hemoptysis were excluded. In all, 905 cases of tuberculosis, made up of 424 males and 481 females, included 220 who had hemoptyses during the active phase of the disease. This is an incidence of 24.3 per cent, regardless of the duration of observation.

Some of the largest hemorrhages in this series occurred in a few patients showing bronchiectasis or rheumatic heart disease. Bogen, including instances of streaks and clots, found that over half his patients with hemoptysis expectorated less than 2 ounces of blood. The present study records 106 cases with hemorrhages of stated amount, ranging from 1 dram to 2 quarts, the average being 5 ounces. This did not include repeated bleeding from the same individual on the same or subsequent days, since these were not thought to be distinct episodes, but more or less a continuation of the first. In approximately 40 per cent of the cases the episode of hemoptysis was repeated at least once.

Hemorrhage was the presenting symptom, often the initial evidence of trouble, in 60 cases. Perhaps nothing drives a patient to seek medical advice faster than the expectoration of a single mouthful of blood, although 23 patients did not bring their initial hemorrhage.

When the local physician was consulted by persons with hemorrhage in cases of previously undiagnosed tuberculosis 70 per cent were properly diagnosed, and it is estimated that 84 per cent correct diagnoses could have been reached by further study.

Only 49 cases in the entire hemoptysis group failed to show a cavity on x-ray examination, and of these, 11 were found to be nontuberculous. No less than 83.4 per cent of the tuberculous cases with hemorrhage had a positive sputum. Of the 170 patients in this latter category, 159 had roentgenograms revealing consolidation, honeycombing, punching out or frank cavitation.

Correlation of hemoptysis with physical exertion, with direct chest trauma or with mechanical disturbance of the lung is possible in some cases, although hemorrhage may and often does appear when the patient is at rest, perhaps during sleep. In only 28 cases in this study was there either a specific history of a precipitating factor or of its absence. In 10 patients hemorrhage was related to one or more menstrual periods.

Among the graver consequences of pulmonary hemorrhage must be listed strangling and asphyxia from massive bleeding, fatal blood loss in the cachectic patient, and the commoner and ever-present danger that blood from a cavity that is generating a positive sputum will spread the infection to other parts of the lungs, giving rise to an acute tuberculous bronchopneumonia or a massive caceous pneumonia. Obviously, repeated episodes of blood-spitting multiply the chances for such complications to occur.

Summary and Conclusions

In a study of 1000 sanatorium tuberculous patients it was found that hemorrhages occurred in 24.3 per cent of them.

The average size of hemorrhage was 5 ounces. Forty per cent of hemorrhages were eventually repeated.

In 60 patients, the first remarkable symptom was hemoptysis.

Seventy per cent of cases with a history of hemorrhage before diagnosis were properly diagnosed by the local physician, when he was consulted. Thirteen per cent, however, were misdiagnosed.

Most tuberculous patients with hemorrhage have cavitation visible on x-ray examination; 83.4 per cent of this series had a positive sputum.

Trauma to the chest, strenuous exercise, mechanical disturbance of the lungs and, in females, the menstrual period are definite precipitating factors.

Small hemorrhages often occur from early lesions at the height of the catarrhal and toxic symptoms that probably signify softening. These are not usually serious and may, in the long run, be beneficial if they call attention to an undiagnosed tuberculosis. The larger hemorrhages that occur in chronic ulcerative tuberculosis, however, although rarely immediately fatal, are accompanied by many unpleasant and dangerous possibilities. Of the 12 deaths that occurred in the sanatorium after hemoptysis, it is thought that 5 were directly or indirectly the result of the hemorrhage. — Reprinted, in part, from *Tuberculosis Abstracts* (January, 1944).

NOTE

Dr. Bennett F. Avery, dean of Boston University School of Medicine for the past three years, has recently been appointed director-general of public health of Iraq. Since Dr. Avery was formerly a resident of the Near East, he is well fitted to assume this new responsibility. Although the date of his departure from the United States is indefinite, he has already severed his connections with the medical school.

CORRESPONDENCE

DYSENTERY

To the Editor: I was quite interested in the editorial "Dysentery" in the January 6 issue of the *Journal*.

Under the conditions the diarrheal diseases render their separation difficult. The incidence of the dysenteries in the military service are specifically diagnosed, and I doubt if the rate is any better in civil life. As expressed in a recent paper [*Dysenteries and diarrheas. War Med. 4: 459-464, 1943*], I do believe, however, that a practical differentiation of noninflammatory diarrhea from inflammations of the intestine can be made by a simple examination of the stool for exudate, and in many cases this examination will indicate the proper treatment before a therapeutic test is instituted.

I should also like to suggest that the use of emetine makes a much more satisfactory therapeutic test for amebic infection with symptoms than does that of either carbarsone or yatren, both of which require a considerable number of days before the therapeutic effect is evident.

NEED FOR MEDICAL AND SURGICAL SUPPLIES

To the Editor: There is a critical need for medical and surgical supplies that may lie hidden and forgotten in physicians' offices; discarded or tarnished instruments, surplus drugs, and other medical supplies. Collected, packaged and distributed, they can be of great help to the armed forces.

Surgical instruments and medicines are hungrily snatched by the medical corps of our allies. The work of war-zone hospitals and welfare agencies is too often crippled by the lack of medical supplies. Community nurseries in this country, and refugee camps abroad cry out for vitamins and baby foods for their ill-nourished charges.

The committee's roll call of medical requests — not one of which has been turned away — reads like a world geography: the Fighting French in North Africa and Tahiti; the Royal Norwegians in Canada and Iceland; the West Indies; South and Central Africa; China; India; Great Britain;

Yugoslavia; Greece; Syria; Russia; Alaska; and, of course, the United States.

To meet the demands that pour into headquarters, the committee needs all types of instruments, especially clamps, scalpels, forceps and all kinds of drugs, from iodine to sulfonamides. By contributing what they can spare, physicians will help speed another shipment of sorely needed medical aid.

FLUORINE AND DENTAL HEALTH

To the Editor: In recent numbers of the *Journal* there have appeared a report of a committee of the Massachusetts Central Health Council, entitled "The Dental Needs of Massachusetts Children of Today," and also two editorials, one referring to this report and the other dealing with a council report, "Problems of Local Health Officers." It is a great satisfaction to find the *Journal* so willing to publish this important report, and to lend editorial comment to the fundamental work that the council is doing.

I doubt if all your readers know exactly what the Massachusetts Central Health Council is, even though the Massachusetts Medical Society is a member. It is composed of about a score of organizations, both official and unofficial, that are carrying on work relating to public health on a statewide basis. These include the Massachusetts Department of Public Health, the Massachusetts Department of Labor and Industry, the Massachusetts Medical Society, the Massachusetts Public Health Association and similar agencies. It also includes as constituent agencies, city or town councils that themselves represent on the local level the same kind of "organization of organizations" formed for the purposes of co-operation, deliberation and collective action. Such organizations represent democracy at work in public health.

I want, especially, to make a brief comment on the report of the Dental Committee and the editorial thereon. As one concerned primarily with public health I have been greatly interested in the possibilities of the application of the recent work on fluorine and its relation to dental health as a community project. Here for the first time we seem to have a genuine prophylactic for dental caries that can be promoted as a public-health measure. The report itself devotes a short paragraph to this most important possibility, and the editorial does not even refer to it.

As in the case of cowpox virus, nature seems to have anticipated science, and the preventive phenomenon has been operating in certain communities for generations before being interpreted by McKay, Dean and others. It now seems well established that in amounts of one part per million and over, fluorine in drinking water reduces the prevalence of dental caries. In amounts appreciably above this it causes discoloration or dental fluorosis (so-called "mottled enamel"), with its accompanying disfiguring effects, but still showing a strikingly lowered incidence of caries. By analysis of the teeth of persons and of experimental animals it has been shown that fluorine in water or other articles of diet is metabolized, or in some manner incorporated into the tooth structure, presumably making the enamel more resistant to acid corrosion due to fermentation by *L. acidophilus*.

It also seems to be well established that the topical treatment of the teeth with fluorine compounds has a similar inhibitory action against caries. Therefore, private dentists and dental health clinics have at their disposal a true prophylactic that may be used for the benefit of the patient.

There remains the problem of whether fluorine in prophylactic amounts has any undetected deleterious effects of a cumulative nature, as well as the question of the control of dosage. Since a large number of people have for many years been exposed to public water supplies containing fluorine greatly in excess of the proposed prophylactic concentration, it should be possible to analyze the vital statistics of these populations and to examine the present physical state of health of these people in order to find the answer to the first question reasonably soon. The question of dosage in water seems relatively simple, since equipment similar to that now used for chlorine will serve. Even adjustment of dosage to

meet the requirements of the relative water consumption at different times of year could be provided.

Fluorine in finely ground bone meal as a universal constituent of the diet has similar possibilities.

The topical treatment of the teeth with fluorine is strictly a dental practitioner's problem, which will surely be explored by that profession.

Of course, caution is indicated in any procedure that affects the general public health, and we must be as sure as we can be that a prophylactic measure will not boomerang. Nevertheless, there must be some venture in every new public-health or medical practice, and we must weigh the gains against the possible risks. Perhaps we have been more guilty of caution than daring in some cases — witness the lag in accepting pasteurization, for example.

I am confident that we have at last a weapon for the practice of public-health dentistry. We shall, in a few years, provide for the incorporation of fluorine in some universal article of diet, and local application of this chemical will become common. Let us be ready and not block this great beneficent discovery of a means of attacking man's most ubiquitous disease by any false prejudice or supercaution.

PROPOSED EXTENSION OF THE SOCIAL SECURITY PROGRAM, WITH SPECIAL REFERENCE TO HEALTH AND MEDICAL ASPECTS*

I. S. FALK, PH.D.†

WASHINGTON, D. C.

HISTORICALLY, it is peculiarly fitting that this conference should consider the health aspects of social-security plans. It was here in Massachusetts that the public-health movement of the United States received much of its first great impetus. And it is especially significant that in the classic *Report of the Massachusetts Sanitary Commission* (1850), Lemuel Shattuck saw and showed clearly not only the interrelations among poverty, sickness and dependency but also the potential role of health services in the welfare of society and the pursuit of happiness.

In the ninety-three years that have elapsed since the appearance of the Shattuck report, there have been advances in environmental sanitation and other aspects of public health that have transformed society. Medicine has become a science and has attained high levels of effectiveness. But it remains to organize the health services so as to assure the availability of modern medical services to all who need them and can benefit from them. The proper test is not that health is better today than it was a decade or a generation or a century ago or than in some other country, nor that medicine and public health accomplish more now than they did then. By such comparisons, health provisions were good in 1900 and perhaps even in 1850. The valid test is whether we do well and effectively today what we know how to do and can do. By this test there is no ground for complacency.

For this audience it is unnecessary to review the fundamental importance of health measures and of medical care in the prevention of destitution and in the building of a strong and democratic society. You see in your own work the extent to which sickness, disability and postponable death destroy the economic independence of persons and families. You know that much suffering and dependency could have been prevented by adequate and timely service. You are aware of the opportunities for therapy or rehabilitation that are missed because there is no

way of paying for needed services. Those of you who have been especially concerned with the problems of children know to what extent society is failing to utilize modern medicine to protect and strengthen the generation that will soon inherit this country.

The public was shocked by the number of young men — about half of the first 3,000,000 called up to serve in the armed forces — who were rejected because of diseases and physical defects, many of which could have been prevented or were still remediable. There is a widespread and insistent public demand that these and similar conditions shall not continue: that this country shall come into the heritage of health services and health security made possible by the progress of science and the wealth of the Nation's resources. This demand has not come primarily because of new or startling discoveries in the laboratory or clinic. It has emerged, by almost imperceptible degrees, from public education — from knowledge of what modern medicine can do through effective and general application, and from awareness that there are ways of accomplishing such application. It is therefore not surprising that the demand for strengthened and broadened health services takes practical form within the framework of plans for social security.

The fullest measure of security rests on the assurance of opportunity to work and earn a living in an economy organized to produce abundantly. To whatever extent this goal is met, social security must also include provision for continuity of income during periods when family livelihood is threatened by sickness or by the unemployment or premature death of the breadwinner, or by his disablement or retirement in old age. World-wide experience has shown that social security in this narrower sense of income maintenance can be most effectively attained through comprehensive contributory social-insurance measures supplemented by public assistance to meet individual needs. New plans for social security will not be complete or economically sound unless they include measures designed to make avail-

*Delivered at the Massachusetts Conference of Social Work, Boston, December 2, 1943.

†Director, Bureau of Research and Statistics, Social Security Board

able to every member of the community certain basic services — among the most important of which are the health services.

* * *

The objective of an adequate health program for these times can be simply stated. There must be assured for all persons access to all essential services, including both preventive and therapeutic services, according to the medical need and without regard to their ability to pay at the time the services are received.

With some important exceptions to be mentioned later, this country has in peacetime a nearly adequate volume of medical facilities and a nearly adequate number of physicians. Unfortunately, neither the facilities nor the medical personnel is distributed throughout the country entirely in relation to the need for services. Moreover, the existing resources of facilities and personnel are not in fact available to large numbers of persons who cannot surmount the barrier of costs that stands between them and the doctor, the laboratory or the hospital. Large numbers of persons go without badly needed care, hesitant to undertake financial burdens or, where these are available, reluctant to accept charity or free services. The practice of modern medicine, moreover, calls for the use of a variety of necessarily costly laboratory technics and specialized skills and equipments that are not available in the office of the ordinary physician. With every passing year, medicine becomes a more intricate and more complicated science, demanding the co-ordinated skills of general practitioners, specialists, laboratory technicians and the hospital. The modern medical schools train young men and women to practice co-ordinated medicine, as members of groups and teams. Yet — outside hospitals — medicine continues to be practiced primarily by more or less isolated persons. Although organized practice develops, its growth is at less than a snail's pace. Each advance in medical science underscores the need to solve problems relating to the costs of medical care and the need to co-ordinate services.

The financial solution — access to needed services without barriers of cost — may be attained through either of two major patterns. Both community health services and personal medical care may, like education, be provided as a public service. According to this pattern, governmental agencies would finance the program from general tax revenues, and would provide all needed facilities and hire all needed personnel. Every member of the community would be entitled to call on these services to whatever extent he needed them. This would be "public medicine" or "state medicine" — using these as descriptive terms rather than as emotional epithets. There is a great deal of "public medicine" now, and its volume grows steadily.

On the other hand, the community health services alone — sanitation, control of communicable diseases and other public-health measures — might continue as government services, supported from general taxation, whereas medical services for the individual would be provided through a contributory social-insurance system. In this case, medical care would be financed through regular contributions to a social-insurance trust fund made by all employed workers — whether self-employed or employed by others. These contributions would entitle insured workers and their dependents to receive all needed services without further payment; the doctors, laboratories, hospitals and other groups would be paid for their services by the social-insurance fund. Contributions might also be made on behalf of other groups in the population, — social-insurance beneficiaries, recipients of public assistance, persons engaged on public works projects and persons in the armed forces, — who would thus become members of the social-insurance system and entitled to medical care on the same basis as workers who have contributed from their earnings. Thus, virtually the entire population would receive medical service through the social-insurance system.

It will be readily appreciated that the first of the two major alternatives — public medical service — would involve the more extensive changes in present medical practice. Many persons argue that because it offers the greater — perhaps the only — assurance that medical care will be available to everybody who needs it, public medical care is the alternative to be preferred. In countries where modern medical facilities and trained personnel are limited, government provision of hospitals and clinics and operation of these facilities with salaried medical personnel may offer the greatest promise of speed and effective health protection. For the United States, however, it might not be considered so practicable or, at any rate, so acceptable a pattern.

At all events, directing my attention primarily to social-insurance possibilities, I shall not explore farther the possibilities of a general public medical service. I shall discuss at this time only the question whether all the major objectives can be achieved through co-ordinating community health services provided by general tax funds and individual medical care financed through social insurance. A properly designed social-insurance system, built on existing medical practices and arrangements, could assure access to needed medical services for 90 per cent or more of the population at the outset, and eventually for every group that should obtain the services through the system. Such a plan would have a solid financial foundation.

The medical services of a comprehensive social insurance system should, of course, be co-ordinated with cash benefits, which assure continuity of income when earnings are interrupted by temporary or permanent disability, thus providing the means

subsistence without which medical care may be meaningless.

* * *

If the objectives discussed earlier are to be achieved, the social-insurance system must cover all workers. Building on the present old-age and survivors' insurance system, it might be said that in addition to the employments now covered, it should include agricultural labor, domestic service, government employment, employment for nonprofit institutions, self-employment in both agriculture and business and miscellaneous employments now excluded. With such a coverage, the insured workers and their dependent wives and children would normally constitute about 85 per cent of the population. As suggested earlier, other persons — such as the needy and the social-insurance beneficiaries — might be qualified to receive medical care through contributions to the social-insurance system made on their behalf.

Under a unified social-insurance system of which medical-care insurance was a part, there would need to be only a single contribution to the insurance fund for all types of benefits. Employers would submit one pay-roll report, and self-employed persons a single report of income. The same earnings records would serve for determining rights to any type of benefit. The funds available for particular types, however, might be segregated. It would probably be necessary to set aside a definite proportion of the contribution income to pay for medical services.

Ideally, the social-insurance system should include provision for any needed medical service — services of the general practitioner and the specialist, use of laboratory and x-ray facilities, hospitalization, dental care, home nursing and prescribed drugs, medicines and appliances. At the outset, however, it might be necessary to provide more limited benefits — not because people are unwilling to pay for all types of services, but because facilities and trained personnel are lacking to furnish some of the services to all persons who need them and who would seek them if the present barriers of cost were removed. This is the situation particularly with respect to dental care. Home nursing presents similar problems, in addition to the need for extensive adjustments in the arrangements under which the service would be furnished. Consequently, it would be wiser to omit these services at the outset, but to provide for their inclusion as soon as practicable. It may also be undesirable for the social-insurance system to meet the costs of any except unusually expensive medicines and appliances.

With these limitations, the insured worker and his family would still have access to a group of medical services that lend themselves to sound integration: care from the family physician, together with specialist services, laboratory and other diagnostic and therapeutic facilities, hospitalization and

unusually expensive prescribed medicines and appliances. This limited program provides a suitable base from which to build toward the more comprehensive provisions. Initially, an amount equal to 3 per cent of pay rolls would probably suffice to furnish insured persons with the guaranteed services and commodities, and to provide adequate remuneration to doctors, hospitals, laboratories and others.

In a nationwide, comprehensive system of social insurance there must be central determination of policies and standards to assure equitable treatment of all members of the system. But the actual administration of the social-insurance benefits should be highly decentralized. Benefits would be claimed at or through local social-insurance offices, and all determinations requiring knowledge of local conditions or personal circumstances should be made in the local communities.

In the case of medical-care benefit, it is particularly important to distinguish between the functions of centralized policy making and decentralized operation. In the first place, the social-insurance system would build on existing facilities, personnel and arrangements, utilizing existing practitioners, hospitals, laboratories and other personnel and facilities. It need not and should not interfere in any way with the essential professional aspects of medical practice or with the internal management of hospitals.

If medical-care benefits were to become available, most persons who had a family physician would presumably continue to go to him. Others would select a physician from among all those available in the community. The only essential change that the insurance arrangement makes between physician and patient is in the method of payment. Instead of paying for medical service at the time it is received — when perhaps he can least afford it — or incurring a heavy debt, or unwillingly accepting free care or going without needed care because he cannot pay, the insured worker would pay for medical care for himself and his family by small deductions from his earnings when he is employed. Instead of each family's carrying the cost of its own care, whether that cost were extremely light or unbearably severe, every worker would pay only his proportionate share of the average cost. Every employed person can afford to contribute an average percentage of his earnings; it is the unequal incidence of medical costs that makes them a burden to the individual and a threat to family security.

Just as each worker could choose his physician from among all licensed practitioners of medicine who wished to participate in the insurance arrangement, so every physician would have the right to accept or reject patients. Social insurance would enable the physician to engage more fully in the practice of medicine, utilizing all modern technics and laboratory aids, and calling on specialists for

advice or service when needed, without concern for the patient's inability to pay. The physician would also know that he would be paid for all his services to insured persons.

The arrangements to pay physicians might take several forms, among which those in each locality would choose whichever they preferred. Physicians might be paid according to established fee schedules for each home visit, office visit and so on. Fee schedules could be uniform for the entire country or might vary from one region or place to another, taking account of variations among communities in customary fees and in overhead costs of practice.

The method of payment that has come to be preferred by physicians in Great Britain, after considerable experience with fee schedules, is known as the capitation method. Under this method the physician receives a fixed amount per year for each person who chooses him, whether he is called on to give much or little or no service to any particular patient during the year. This method requires that every insured person specify his intention to be on some physician's list. So that physicians will not lose income to which they are entitled, capitation payments are made not only for those who have chosen a physician but also for those who have not. Such payments and adjustment are, of course, made locally and not from the central office.

Physicians who so choose might be paid on a salary basis, whole time or part time; or a combination of various methods might be used. Provisions should also be made for equitable payments to organized groups of physicians.

The hospitals, like the physicians, should be free to choose the method by which they would be paid. In discussions that we have had with hospital administrators and official committees of the hospital associations, it has been generally agreed that payment should be made direct to the hospital, whether by assignment of a fixed benefit amount for each day of hospitalization or by payment of the reasonable cost of minimum necessary services, within fixed minimum and maximum limits. The method of payment to hospitals should not and need not interfere in any way with the hospital's control of its own customary management and affairs.

With such a general framework for medical services furnished through social insurance, the current pattern of professional relations among people, doctors and hospitals would not be changed in any basic way. This is the virtue of health insurance to those who wish to build by slow and measured evolutionary processes on the status quo.

* * *

If the approach to a health-insurance plan is primarily with respect to existing financial problems, the tendency is to leave treatment of the qualitative problems largely to the operation of *forces and trends* working within the professions. This is not to say,

however, that an insurance plan designed along these lines should be or can be indifferent to the need for safeguarding and constantly improving the quality of services provided as insurance benefits. On the contrary, when contributions are compulsory, government cannot avoid responsibility for the quality of the benefits.

In a system that builds on the existing and available resources in professional personnel, hospital and other facilities, I suggest that at least the following six provisions are essential to protect and promote the quality of the medical services: access to necessary specialist and consultant services; specific rates of payment for services of the specialist when furnished by physicians who meet professional standards certifying their special skill; access to necessary laboratory and related aids to diagnosis and treatment; payments for hospital care furnished in institutions that meet medical and hospital professional standards applicable to institutions offering general or limited varieties of service; specifications that aid the development of organized group practice and co-ordinated medical, hospital and community health services; and financial support for professional education and for research.

In establishing professional standards, the insurance system should obviously be expected to lean heavily on standards developed by professional organizations. A competent advisory council, with adequate professional representation, would be essential.

The professional specialty boards have already done basic spadework in certifying most of the qualified specialists in medicine. Large problems remain, but desirable solutions can undoubtedly be found by administrators working in close collaboration with advisory bodies.

In designating hospitals entitled to receive payments, the social-insurance system may be guided by existing accrediting procedures long accepted by the Nation's hospitals. Institutions that cannot meet all the standards applicable to large urban or metropolitan hospitals might nevertheless be accredited for all or limited varieties of cases, if the service were adequate to promote the health and safety of the hospitalized persons. The social insurance system might also encourage the development and use of qualified institutions for the care of the chronic sick or of corresponding facilities associated with general hospitals, thus providing more appropriate treatment for chronic patients and reserving the more elaborate and more expensive facilities of the general hospital for acute cases.

General policies for the acceptance of participation by hospitals, the designation of specialists and the arrangement for paying doctors and hospitals should be determined centrally for the social-insurance system. These are functions of the administrative body, guided or directed by consultations with appropriate professional and other advisory bodies. Appropriate

Education of those policies, however, should be carried out through a thoroughly decentralized administration, operating at every level of administration, from the central to the local, with the help of advisory bodies that include representatives of the persons who furnish and those who pay for the benefits.

I have stressed the point that a social-insurance system would be built on existing facilities and existing arrangements for medical care, changing primarily the methods of payment. I do not wish, however, to give the impression that the health services would remain in their present stage of development. By striving to give every physician access to all necessary diagnostic and therapeutic aids in the treatment of every patient, whatever that patient's economic circumstances, the system would advance the practice of medicine toward the standards that now prevail in the better hospitals and clinics. By removing the barriers of cost that today cause many persons to postpone seeking medical advice, it would stimulate early diagnosis and treatment and thus aid in the prevention of much illness and disability. By guaranteeing physicians fair payments for their services, it would enable them to practice in areas and communities that at present cannot provide them with a decent living. By guaranteeing payment for hospital service, it would encourage the building of hospitals and health centers in communities that can find the capital funds for such construction if they are assured of a continuing operating income.

There is an additional obligation to take certain direct measures to improve the adequacy of existing health and medical services. Either from the social-insurance funds or from other public funds, money should be made available to construct hospitals and health centers in communities that cannot raise the necessary capital. Moreover, as indicated before, to advance the skill and knowledge that will promote prevention of disease, and to assure progressive improvement in the quality of medical care, the social-insurance system might properly set aside a small fraction of the income from contributions for the support of research and of professional education and training.

* * *

Among physicians who accept the need for medical-care insurance, some will criticize the plan outlined here as far too conservative and too timid. In particular, this group will object especially to permitting fee for service as one method of payment.

There is little doubt that some of the most serious deficiencies of present-day medical practice result from the fee-for-service method of payment, because it discourages early, preventive or adequate care — especially among people of modest means — at the same time that it puts a premium on excessive treatment in some cases and inadequate treatment in others, and on various types of fee-splitting prac-

tices. Some of these objectionable features would be carried over into the insurance system, despite precautions that might be taken. Although the patient would no longer be barred from needed services, there would be a risk that some physicians would load unwarranted service charges on the insurance fund. Since the aggregate amounts available for all payments to physicians would be limited, the result might be a competition for patients and for volume of services almost as inimical to professional standards as that which occurs today. Through the downward proration of physicians' bills if they are excessive, the insurance fund can be protected against extreme unwarranted costs. For the rest, the problem would be largely a matter of intra-professional controls.

Practitioners here, like those in Great Britain, would probably turn to a capitation or a salary basis of payment, because they would learn by experience that these methods are more satisfactory for them as well as for their patients. Nevertheless, I do not agree that the insurance system should bar the fee-for-service method. So long as a majority of physicians prefer or insist on a fee basis, it should be accepted by the social-insurance system. At the same time, it should give full opportunity for the development of organized group practice where this arrangement is preferred by physicians and insured persons. In other words, the insurance system should build on what now exists, and at the same time should build toward better arrangements by leaving latitude for change and improvement as rapidly as change is desired by or is acceptable to those who are most concerned.

Certain misleading criticisms of medical-care insurance that are being broadcast across the Nation can be dismissed in a few words.

In the first place, medical benefits furnished through social insurance are not "free medicine" or "free care." It is of the essence that social insurance is contributory, and that people pay for what they get.

In the second place, expenditures for medical care through social insurance need be no greater than the amounts the population already spends in a hit-or-miss fashion. In supporting a larger volume of service and better service, more would be spent for the types of service included as insurance benefit than is customarily spent. Such an increase would be offset by savings from curtailing present levels of expenditures for useless services and services now furnished uneconomically. Moreover, paid in regular, budgeted and average amounts, the insurance costs would not be burdensome or catastrophic for anyone, even if in the aggregate they were somewhat larger than the total amount now spent individually for medical care. They would be absorbed in an orderly fashion into the streams of the social economy, just as the contribution costs of workmen's compensation, old-age and survivors in-

insurance and unemployment compensation have been absorbed.

Thirdly, the medical-insurance system would not destroy the private practice of medicine. It would strengthen and preserve its really essential elements — competition for patients or for annual income on the basis of satisfactory service, not on the size of a fee; free choice of his physician by the patient and the right to change to another; the right of the physician to accept or reject patients; the right — and also the obligation — of the profession to participate in the determination of all matters of high policy that affect medical practice; and the opportunity of the practitioner to be wholly concerned with his patient's medical needs irrespective of the latter's pocketbook.

Fourthly, the medical-insurance system would not weaken or destroy the voluntary-hospital system. On the contrary, it would preserve to these hospitals their control over their own institutions and would guarantee them increased and assured continuity of income so that their services to the public could be larger and better.

Last of all, the medical-insurance system need not and should not ignore noninsured needy persons. As pointed out earlier, through payments made on their behalf by public agencies, the needy could be made entitled to the services provided for self-supporting families. Thus, one class of service would be available for all, with dignity and self-respect for the patients, whereas physicians would be released from the concern to distinguish pay from part-pay and free patients. This arrangement would be more satisfactory than present or prospective programs of medical assistance, even with the improved financial arrangements under the Social Security Act already recommended by the Social Security Board.

* * *

With what assurances or what hopes can one look forward to more adequate health protection than the people of the United States now have?

The formulation of objectives and methods is only the beginning. A specific program of action was recently proposed to Congress through a bill (S. 1161) introduced in the Senate by Senators Wagner and Murray and in the House (H.R. 2861) by Representative Dingell. This bill is notable in that for the first time it sets forth a comprehensive national program of contributory social insurance, including provisions for medical care in sufficient detail to provide a basis for public discussion. Submitted by its sponsors not as a final blueprint but as a basis for public discussion, its proposals deserve and invite thorough consideration, reasoned debate and constructive criticism.

I believe that the great majority of the people of this country know that the objectives of medical-care

insurance are sound; they want more nearly adequate service and are prepared to pay for it. The public and all the agencies of the Government most directly concerned — legislative and executive — need the help of persons with a professional background and knowledge to bring to light what is unsound in any specific plan that is proposed, and to discover what sound and constructive changes are desirable.

There is not much time for public education and discussion if the opportunity of achieving a comprehensive and well-designed system of social security in our time is to be grasped. If action is postponed until the potential disruptions and crises of the postwar period are upon us, we may find ourselves with a hastily devised and inadequate relief program, rather than a soundly conceived social-insurance system. Once the general principles of a social-insurance program have been agreed on, time is needed to work out detailed plans and procedures and administrative machinery. It would probably be possible to move fairly rapidly in extending the cash-benefit system, for which a substantial framework already exists. No responsible administrator would, however, want to begin operation of a medical-care-insurance plan until he had had adequate time for consultation with all the professional and lay groups whose interests and knowledge and skills should be utilized in developing detailed policies and procedures.

A period of full employment like the present is the most favorable time for initiating a contributory social-insurance program. The initial impact of the contributions can be more easily borne by workers and employers than at any other time. The new contributions will have a deflationary effect on the social economy whenever a beginning is made. Deflationary pressures are needed now; they might not be wise in the immediate postwar period.

If social-insurance coverage is extended to all types of employment during the war, the great majority of the workers will come to its end with right to cash benefits for themselves or their dependents in case of unemployment, sickness, disability, retirement or death, and with access to medical care for themselves and members of their families. If extension of the system is postponed until a period of limited employment, it may be years before large groups of workers can qualify for insurance protection.

If it is decided now that medical-care insurance is wanted, and if the detailed plans are developed now the tens of thousands of physicians and surgeons who are serving in the armed forces will, on their return, find opportunities for civilian service, with more latitude for choice as to how and where they will serve than they have had before. If each returning physician must make his way back into practice wherever his chances seem best for establishing an adequate livelihood, it may take a long time to bring

about a relocation of physicians and medical facilities in accordance with the needs of the population.

Now — before the war ends — is the time to plan the peace for the years ahead. Such planning must be world-wide. But it must also be national and local. And it must comprehend not only political security but economic and social security — freedom from

want and from the fear of want — in order that men may live lives of dignity and human worth. Social security thus appears as a necessary condition for men to be free and independent.

There is increasing recognition that health protection would be among the most valuable, the most potent for the future, of all the benefits from a comprehensive program of social security.

THE BLUE CROSS, THE BLUE SHIELD AND THE WAGNER-MURRAY-DINGELL BILL*

NATHANIEL W. FAXON, M.D.†

BOSTON

PREPAYMENT insurance for protection against the cost of sickness is generally accepted as sound. The hospital plans of the Blue Cross, started a little over ten years ago, now operate in thirty-six states and the District of Columbia, which contain 87 per cent of the population, with over 13,000,000 subscribers. The medical plans of the Blue Shield started later, are now operating in thirteen states, which contain 50 per cent of the population. Both organizations are growing rapidly, with subscribers from both urban and rural areas. Both are on a voluntary basis and are nonprofit organizations operating under the direction of state insurance commissioners but controlled by directors, a majority of whom are representatives of hospitals in the case of the Blue Cross, and physicians in the case of the Blue Shield. Thus, both are directed by those most interested in the success and progress of these bodies.

There is not much use in proclaiming the virtues of something that is already accepted as admirable. Almost everybody agrees that the Blue Cross and the Blue Shield are good. But are they good enough? Many persons believe that they are sufficient to meet the need of a method of protection against hospital and medical costs and that they will gradually expand geographically to cover all parts of the United States and will add benefits to cover all medical needs. Admittedly, this will be a gradual evolutionary process, elastic enough to fit every area and every changing need.

Others say that voluntary plans, dependent on personal volition, will never adequately protect the community against sickness. They hold that such plans are too slow in operation, pointing out that in ten years only 13,000,000 out of a possible 80,000,000 persons have availed themselves of the Blue Cross; that many who need protection will never avail themselves of it; that the Blue Shield is too limited in benefits to give satisfactory protection; and that it will be necessary either to supplement voluntary plans with compulsory plans or, better still, to replace

these imperfect voluntary plans by a comprehensive, compulsory plan embodying medical care in the home, office and hospital, together with such hospital care as is needed.

We are now called on to face this problem of the comparative merits of voluntary and compulsory health insurance through the submission to Congress of the Wagner-Murray-Dingell Bill, which proposes such a system of compulsory health insurance as part of a unified national insurance system for the entire United States.

What is the Wagner-Murray-Dingell Bill? To estimate its value intelligently, which incidentally will help one to decide on the merits of voluntary and compulsory insurance, one must at least understand its essential provisions. For the purpose of this discussion the following are the most important factors. The introduction to the bill reads as follows:

To provide for the general welfare; to alleviate the economic hazards of old age, premature death, disability, sickness, unemployment and dependency; to amend and

and extend the social security rights of individuals in the military service [they are not protected now]; to provide insurance benefits for workers permanently disabled; to establish a federal system of unemployment compensation, temporary disability, and maternity benefits [now under state control]; to establish a national system of public health service; to establish a federal system of medical research; to advance the advancement of knowledge and skill in the provision of health services and in the prevention of sickness, disability and premature death [this is extension of public-health services and financial assistance to medical schools and medical research]; to enable the several states to make more adequate provision for the needy aged, the blind, dependent children, and other needy persons; to enable states to establish and maintain a comprehensive public assistance program; to amend the Internal Revenue Code.

Concerning the intent of this bill to improve living conditions in the United States and to make this a happier land, there can be no doubt and no opposition. The question is whether the method will accomplish the results desired. To determine this the general principles underlying the operation of the provisions of the bill must be reviewed and its specific measures examined. The primary concern here is with the medical and hospital section.

*Delivered at the Massachusetts Conference of Social Work, Boston, December 2, 1943.

†Director, Massachusetts General Hospital.

Perhaps the most important item in the bill is that of federalization. Can the federal government do this better than state governments? In some ways it can; for instance, such federalization assures similar application in benefits in all states, whereas at present there is variation in the action of security boards in different states. On the other hand, can a centralized organization ever understand and adjust its rulings and methods to meet satisfactorily the varying local conditions of forty-eight states? Will the resulting bureaucracy that must of necessity be created by such federalization further accentuate the already alarming number of federal employees, with the corresponding dangers of political patronage and the party coercion of voting powers?

Certainly this bill presents a fascinating blueprint of governmental paternalism, professing a most kindly interest in the economic welfare of its citizens and setting up an attractive medical and hospital structure to provide for care in sickness and to develop preventive measures. Again, there can be no quarrel with the desirability of the goal or the intent; the only question is whether the result can best be obtained in this way. It is a pretty picture, but is it a true one?

What are the essential points of the medical and hospital section? Title IX provides:

Every individual who is currently insured and has been found by the Board to be eligible for benefits under this title in a current benefit year, shall be entitled to receive general medical [that is, medical care in home, office or hospital], special medical [that is, care by surgical and medical specialists in home, office or hospital], laboratory and hospitalization benefits.

Moreover, all dependents of the insured receive the same benefits.

The administration of all this is placed under the Surgeon General of the Public Health Service, who is authorized to negotiate agreements with appropriate agencies of the United States, or of any state or public or private agencies, or with private persons, to utilize their services and to pay fair, reasonable and equitable compensation for them; that is, he may select physicians, specialists and hospitals. The National Advisory Medical and Hospital Council is set up with the Surgeon General as chairman and with sixteen members appointed by him from a panel of names submitted by professional and other agencies and organizations connected with medical services and education and with the operation of hospitals, and from other organizations informed on the need for or the provision of medical, hospital and related services and benefits. This council is authorized to *advise* the Surgeon General. All physicians legally qualified by a state shall be qualified to furnish services; that is, if they wish to and are accepted by the Surgeon General. Every person may select his physician from those accepted by the Surgeon General, subject to the consent of the practitioner selected; that is, there is a free choice of physicians.

Specialists, however, shall be named by the Surgeon General, and their services shall "ordinarily be available only upon the advice of the general practitioner."

A fee schedule shall be set up by the Surgeon General, established on a per capita basis or a salary plan, or a combination of these — a provision that places great power in the hands of the Surgeon General. He may also limit the number of potential beneficiaries for whom a practitioner may undertake to furnish general medical benefits or distribute them, if the per capita plan is used, on a pro rata basis among practitioners. Thus he can control the amount of work any physician may do as regards this plan.

In a similar manner the Surgeon General shall select participating hospitals. The bill fixes the amount that may be paid for hospital services, to be "not less than \$3 and not more than \$6 per day for thirty days" and after that "not less than \$1.50 nor more than \$4." Payments are made to beneficiaries who, however, *may* assign their benefits to hospitals.

What are the general premises and principles involved? What are the underlying needs for such a bill? The Committee on the Costs of Medical Care pointed out that there are four groups of people. The first includes the rich or well to do, who have ample resources to meet the costs of medical and hospital care, with incomes of \$5000 and over. They form 9.2 per cent of the population. The second is the middle class, with incomes of \$2000 to \$5000, forming 35.5 per cent of the population. Voluntary plans have appealed to this group. Third comes the wage-earning group, with incomes from \$1000 to \$2000, forming 41 per cent of the population. Proponents of compulsory insurance believe that this class will never take out much voluntary insurance and must be compelled to protect itself through compulsory insurance. The fourth group comprises the indigent — persons with incomes below \$1000, forming 14 per cent of the population. Many of these are unemployable and will never be able to contribute adequately to any plan; they must be assisted by welfare and given medical and hospital care at public expense.

The difference of opinion regarding the third group is the crux of the matter. Proponents of compulsory insurance believe that these people will never take out much voluntary insurance and must be compelled to protect themselves and thereby the community, through compulsory insurance. Those favoring voluntary methods say that given adequate wages and time to acquaint themselves with the benefits of voluntary insurance and to understand it, this group will rise to the occasion. They cite the facts that most of the automobiles, electric refrigerators, radios, homes and furniture are bought on an installment plan, — that is, by budgeting, — and that people who voluntarily do this are also

bright enough to see the advantages of prepayment health insurance. They also point out that there is an advantage to the community in the development of personal initiative of this sort, of which more later. In rebuttal, the compulsory group says that this plan might work with high wages, but questions its effectiveness in periods of depression. So far as the wage-earners' contributions go, if they are out of work or are on mere subsistence wages neither plan will work, although the compulsory plan has advantages, since it includes the contribution of the employer and the possibility that the government will also assist through contributions from general taxation, thus gaining support from three sources instead of only one. It is well to remember, however, that all the money eventually comes from the taxpayer, be he rich or poor. There is validity to the arguments of both sides; it is a matter of relative values.

One of the principles of democratic government is that "the Government should do only those things that the people cannot do." Wendell Willkie said in his speech at the opening of the Greater Boston United War Fund campaign:

Totalitarianism has an insidious and sinister appeal — an appeal that is by no means limited to those nations where it is completely dominant. It appeals to those who prefer leadership to initiative, blueprints to enterprise, a blind following to freedom. It appeals to those who find it difficult to bend democracy to serve their economic or political self-interest.

The United States was founded on the principle of personal initiative and the participation of its citizens in the affairs and machinery of their government as well as in the prosecution of their livelihood or business. This country has been developed through personal enterprise and initiative, and I, for one, do not believe that the end of the possibilities of these factors has been reached. For instance, the people of Greater Boston pledged \$15,000,000 to the Greater Boston United War Fund in 1943 — a voluntary effort.

Civilization forces restrictions on the initiative and freedom of individuals, but these restrictions are accepted by all but the criminal class, voluntarily and with the understanding and belief that they are for the good of the community and, therefore, for their personal advantage. For example, taxation is a relinquishment of the freedom of spending one's own money as one wishes, as a result of which one obtains certain benefits from the states. Compulsory insurance is a form of taxation. In developing our form of government we have agreed that the Federal Government can do some things better than the states. These activities include the Army and Navy and the protection of the country, the control of currency through the Treasury and the Federal Reserve System, the carrying of mails through the Post Office Department, the Interstate Commerce Commission and the control of epidemics through the United States Public Health Service. It has also been agreed that states can do some

things better than cities. These activities include general laws affecting all residents of the states, the general direction of education, the licensing of doctors, lawyers and nurses, workmen's compensation laws, the care of tuberculous and mental patients (sanitation and state boards of health) and roads and other public works. Lastly, it is agreed that cities and towns can regulate best police and fire departments, local health and welfare matters, schools and local public works. This is all built on the sound principle that the larger unit shall take responsibility only for those things that it can do better than the smaller — and it should be remembered that it all begins with the individual citizen.

Of course there is a wide variation in what cities or states are willing to do. This gives an uneven distribution of public works, public service, regulating laws and so forth. Public works and service, although they offer benefits, cost money that must be raised by taxation. In general, those communities that have the greatest public services also have the highest tax rates. Those communities that want them must pay for them. Federalization of any project means that some communities will have to pay not only for the public services that they now have but also for similar services in communities that do not have them and are too poor or are unwilling to pay for them. It may be argued that it is just that the richer community should help the poorer, and that by its so doing the whole country is benefited and even the doubly taxed richer community receives adequate benefit through the improvement of its neighbor, but let us recognize what is going to take place.

So much for the state. Now what about the individual; how does taxation affect him? Everyone wants freedom and security: freedom of religion, of speech, of work and of spending; security through protection against want, loss of work and unemployment, provision for old age when earning power is lost, protection of dependents in the event of the death of the wage earner and protection against the cost of sickness and the accompanying loss of income.

Apparently, security can be reached only through the voluntary renunciation of some part of freedom. To achieve security for old age, unemployment and sickness, one must give up complete freedom of spending one's earnings. That is, one must pay for it through taxation or save for it oneself. The question is, How is one to do it? By initiative through savings, or by voluntary insurance, or by legislative enactment, through elected representatives, of compulsory insurance, which is taxation? So much for principles. Now let us take a practical view.

Evolution is terribly slow. Voluntary plans will take a long time; perhaps twenty years will be needed to accomplish what a legislative enactment could accomplish in two years. Many people will

suffer during this period from their own lack of foresight and from imperfect plans. There may always be some improvident people who will never protect themselves, who will spend their money willfully and then fall back on the community as indigents. Legislation is quick, albeit revolutionary. But, it may reasonably be asked, since we are progressing on the voluntary road, is it necessary to rush things? After all, Rome was not built in a day. Compulsory insurance will apply to all who need it. It will make medical and hospital care available without direct cost at the time of sickness to all who need it, thus overcoming the unpredictable element in sickness as well as the uneven distribution of such care as is necessitated by limitation of income; that is, more people will get more care. It is urged that the loss of freedom and the cost through contributions are more than compensated by returns in benefits and security. A federal unified system will apply equally to all parts of the United States. Those areas with high tax rates can afford, on the basis of public good, to help the poorer areas. Universal benefit will result. What helps one's neighbor will in the long run help oneself. That is a good Christian doctrine, but what will be the cost?

According to the bill, which is based on statistics collected by the Bureau of Research and Statistics of the Social Security Board, the employee will pay to the unified system 6 per cent of his wages, and his employer will also pay 6 per cent of the pay roll. This applies to all wages up to \$3000 a year. Approximately one quarter of this total is set aside for medical and hospital benefits or, as it is commonly termed, "compulsory health insurance."

The following figures are only approximate and are not official; they will, however, help one to understand the workings of the plan. The estimated normal income of wage earners in the United States is \$100,000,000,000. Twelve per cent of this is \$12,000,000,000. Of this, one fourth, or 3 per cent of the total income, is to be set aside for medical and hospital care. Of this \$3,000,000,000, one third is to be set aside for hospital care, leaving \$2,000,000,000 for medical care. These figures may be too high, but granting a considerable shrinkage it appears that the statistical basis of the plan is reasonably sound and that certainly, so far as hospital costs are concerned, there would be enough money to pay the hospital bills.

How does this apply to the taxpayer? The population of the United States is approximately 120,000,000. The number of wage earners is 30,000,000 or one quarter of the population. With their dependents they total 80,000,000, or two thirds of the population. Take the case of a person earning \$2000 a year; 6 per cent of this is \$120, which will be his direct contribution or tax. But employers also pay 6 per cent, which in time will be added to the cost of production of every article, and so produce a rise in the cost of living for every one of the

120,000,000 persons in this country. The wage earner must eventually pay his share of this added cost for himself and his dependents, and since they form two thirds of the population, he will pay two thirds of this added cost of living, or 4 per cent of the employers' 6 per cent. Consequently, he will pay 6 per cent of his salary in direct taxes and 4 per cent in indirect taxes, or 10 per cent in all. Therefore, his real contribution will not be \$120 but \$200. In return for this he will get old-age pensions, unemployment payments, survivor benefits and medical and hospital care. In addition, he must pay his regular direct and indirect taxes to the federal, state and city governments. It is estimated that at present everyone is paying in one way or another between 25 and 30 per cent of his income in taxes. If this bill is passed he will be paying 35 to 40 per cent of his income. Is it not fair to ask how far this taxation, allocation or checkoff on wages can go and still permit the wage earner to maintain initiative and freedom? To be sure, he gets much in return, but one must ask, "What price freedom?"

It is true that this extra 10 per cent will not all be additional, since both employers and wage earners are already contributing to the Social Security Fund. Present social-insurance taxes are as follows: employers, 1 per cent for old-age pensions and survivor benefits and 3 per cent for unemployment compensation; and employees, 1 per cent for old-age pensions and survivor benefits. Thus the employers are paying 4 per cent of the suggested future 6 per cent, but the employees are paying only 1 per cent of it. Therefore, the employee will pay 5 per cent more as his own contribution, plus two thirds of the 2 per cent increase in employers' tax, or a total of 5 per cent plus $1\frac{2}{3}$ per cent, or $6\frac{2}{3}$ per cent more from his wages than he is now paying.

It is also true that the Social Security Act calls for increases to 2 per cent on January 1, 1944, for both employer and employee to cover old-age and survivor benefits, to $2\frac{1}{2}$ per cent in 1946, and to 3 per cent in 1949. Nevertheless, the point is still pertinent that there will be a substantial increase in taxes taken directly from wages.

The experience of all European plans, of voluntary plans in this country and of university departments of hygiene where students pay a fixed health fee, is that the amount of medical care is increased. Human nature is such that, having contributed, everyone wants to receive some benefit. Granted that more medical care than is now utilized is desirable, it will be well to consider whether the existing number of physicians, nurses and hospitals will be able to meet the demands that will suddenly be thrust on them. This is not an argument against providing more medical and hospital care but rather against a too rapid change from one system to another. After all, medical care is dependent on individual doctors, and hospital care is limited by the extent of hospital facilities. If the amount of

care is to be increased, so must the means of providing it. Promises that cannot be fulfilled lead to exasperation of those who are disappointed. Some check that will control too rapid expansion seems to be indicated.

* * *

If we believe that our present medical and hospital system is satisfactory, that it is developing adequate methods of meeting economic needs, and that it will in a reasonable time supply adequate medical and hospital care to all at costs and by methods within their means, we should oppose the Wagner-Murray-Dingell Bill. If we believe that the present system is unsatisfactory and inadequate and that voluntary plans will never adequately provide medical and hospital care, that the third group outlined above, comprising 41 per cent of the population, will never be satisfactorily protected, we must decide whether we shall achieve this protection through direct general taxation or through compulsory insurance. Between these two choices there is no doubt that compulsory insurance is the better plan. If we decide to have compulsory insurance we may support the Wagner-Murray-Dingell Bill, but, it is to be hoped, with certain important changes. Let us for the sake of argument take the stand that compulsory health insurance is desirable and consider how it would operate under the provisions of this bill.

First of all, there is the problem of federalization of the medical and hospital system; for although the plan begins with qualification of physicians and hospitals by states, if this bill passes it is only a question of time before qualification will become a federal power. Although I deplore in general the concentration of power in federal bureaus, I cannot see anything reprehensible in the federal licensing of physicians and hospitals. I can, however, see great difficulties in centralized bureaus' appreciating and understanding local conditions. There will inevitably be a tendency to set up rules and regulations and to apply them universally, with the result that what is applicable with advantage to conditions in one state may be disadvantageous when applied to different conditions in another state. I can also foresee great possibilities for pressure groups and logrolling deals, since local communities will thereby stand to obtain great benefits at small cost to themselves; witness the efforts to obtain veterans' hospitals.

Without question, the authority granted to the Surgeon General of the Public Health System is too great. Granting the integrity and ability of Surgeon General Parran, and those who have preceded him and will follow him, the concentration in one man of the power to select or reject the physicians and designate or reject the hospitals that may participate in this plan approaches dictatorial powers. May he not under pressure in turn use pressure on these

appointees to influence them in their activities, both social and medical, with loss of appointment as the result of nonconformity?

It seems obvious that there must be nonpartisan control of such power. This could be made possible by changing the suggested advisory committee to a directing committee, which would have the authority to determine policies and principles and to direct the Surgeon General and review his acts, and to which he must report. This committee should not be selected by him but should be composed of representatives selected by those national organizations most competent to judge the quality and quantity of medical and hospital care, and most interested in the successful operation of this project. Such a change would adhere to the well-known principle of organization of having a policy-making body, with an executive to carry out its policies and to report to it. This is the organization of the Government: Congress makes the laws; the President carries them out. It is the organization of corporations: the board of directors makes the policies; the general manager executes them. The Surgeon General of the Public Health Service is the logical executive officer to administer the regulations of such a directing committee. He should not be the chairman.

With control placed in the hands of a directing committee composed of physicians, hospital administrators, dentists, nurses and lay representatives of other interested organizations, many of the controversial subjects in this bill could be cared for; for instance, the method of payment, — whether by fee schedule, a panel per capita plan, or by salary, — and the selection of physicians, the designation of specialists, the acceptance of hospitals and the adequacy of payment for hospital service, since the decision on these matters would be placed in the hands of those who would know the facts and understand the conditions and who would be interested in the success of the undertaking. The acquisition and probable misuse of power would be avoided so far as possible. Nor would the effectiveness of administration by the Surgeon General be prevented, because he would be given free scope to carry out the provisions laid down for him.

The next point is one of omission in the bill. The present hospital system has been successfully built on the general principle of government co-operation and supplementation instead of replacement. Government hospitals — federal, state and municipal — co-operate with and supplement non-governmental or voluntary hospitals in providing care. Furthermore, this system promotes friendly but active competition in producing better care of patients. There should be added to the bill the proviso that membership in a voluntary hospital or medical-insurance plan that provides comparable benefits is acceptable in lieu of compulsory contributions. Compulsory insurance may be required

for others. Admittedly this lays a heavy burden on the voluntary plans, because compulsory plans have the advantage of forced payments from employers. But voluntary plans have the advantage of working under flat rates, which makes them attractive to those earning higher wages. Certainly such a proposition will stimulate competition to see which plan can produce the best results. To compete, the Blue Cross must operate in all states with reciprocity, and the Blue Shield will have to develop rapidly more nearly complete medical benefits. Moreover, — and this is extremely important, — such a provision would adhere to the American principle of encouraging personal initiative and of encouraging thinking and choice on the part of every wage earner. Thereby he becomes a better citizen.

For this bill to be acceptable to most people it must present a rational plan clearly defining how the central regulating federal organization can be decentralized to administer benefits and to adjust general principles and policies to local conditions. Shall this be done by existing state organizations or shall a new board, composed of representatives of all the present state departments involved, with perhaps additions representing interested groups, be set up? A substantial amount of local administration must be guaranteed.

Lastly, it is essential that payments for medical and hospital service be made directly to the physician and hospital and not to the subscriber beneficiary. Only in this way can payment for service be assured. The present permissive statement that beneficiaries may assign payments is not satisfactory.

If legislation is to be enacted it should adhere to certain basic principles: It should disrupt present conditions as little as possible. Therefore, legislation for compulsory health insurance should assist, co-operate with and supplement the present medical and hospital system — not replace it. This means that the principle of private medical practice and voluntary hospital and medical insurance plans shall be specifically recognized and their existence approved. Second, the bill should permit opportunity of choice; that is, the citizen should have a choice between joining a voluntary medical and hospital insurance plan providing comparable protection and accepting compulsory insurance. In other words, membership in a voluntary plan providing comparable benefits should be accepted in lieu of compulsory insurance. Third, the bill should permit the operation on a local basis, through state

organization, of principles and policies developed on a federal basis. In other words, there should be federal guidance and control but local application. In no other way can local conditions and variation be successfully understood and met. Fourth, the bill should place control of any health plan in the hands of those most interested and best informed concerning the quality and quantity of medical and hospital care. To this end a governing or directing committee, composed of physicians, hospital administrators, dentists, nurses, public-health officials and others representing the public, should be created to develop policies and principles to be carried out by their agent, who may properly be the Surgeon General of the United States Public Health Service. Lastly, the objective of such legislation should be to provide medical and hospital service not to provide a cash payment that might be used to obtain medical and hospital care. To achieve this, payments for service should be made directly to the physician or hospital and not to the beneficiary.

If these principles are adhered to, it is safe to present a plan of compulsory health insurance to the people of this country for consideration, for under these conditions freedom of choice and of action is still theirs.

* * *

In conclusion, since I am at heart an individualist since I think that government best that governs least, and since I think that evolution is the safe way to advance, I am emotionally in favor of voluntary insurance and against compulsory plan. Perhaps these emotions are but the conscious components or results of experience. At the same time I cannot find any convincing logical argument against the general principles of compulsory plan only criticism of specific points and a difference of opinion concerning the desirability of doing things that way. Therefore, from the standpoint of reason and logic I cannot honestly oppose the idea of compulsory plans.

There is so much to be said on both sides that perhaps the answer is that each side may be partly right and that the only way to find the truth is through a fair trial. Why not, then, accept a trial of compulsory health insurance, being careful that it does not replace free enterprise in the shape of voluntary insurance, but that it is operated as a co-operative, supplementary plan, with as few undesirable complications of operation as possible. In other words, if there must be compulsory insurance, let this bill be made as nearly perfect as possible through constructive criticism.

PROLONGED CASES OF GRIEF REACTION TREATED BY ELECTRIC SHOCK

ABRAHAM MYERSON, M.D.*

BOSTON

CASE REPORTS

THE 4 cases that are here reported in somewhat disguised form are technically classified under the heading "reactive depressions." In each of these cases, however, the immediate precipitating factor was the loss by sudden death of someone close and dear to the patient, so that the term "grief reaction" has been used to designate the mental state of the patient. Electric-shock therapy was used with such excellent results as to merit their publication.

CASE 1. A 48-year-old, married woman had all her life exercised obsessive scrupulosity — that is, a tendency to examine her own acts under over-rigid criteria of right and wrong. With it she was the victim of what may properly be called excessive religiosity, in that she was constantly praying for guidance under circumstances that would not seem to the ordinary religious person to demand such fervency. She was, however, active and well and without any overt mental disturbance until shortly after her only son died under tragic accidental circumstances. The grief reaction was immediate, and she became obsessed with the idea that she was somehow to blame. The train of so-called "reasoning" was circuitous and involved, and the sense of guilt was extreme, and the religious ideas became mingled with horrible and blasphemous ideas. In other words, the appeals to God, which had been sincere, were mingled with derisive and even obscene thoughts. For example, the word "God" became linked with the word "dog," to the horror of her helpless mind. She developed rituals by which she sought to prevent God from taking vengeance on her for her blasphemous reactions. She became sleepless and emaciated, and the psychosis evolved steadily toward an increasing, agitated depression, with obsessive thoughts and compulsive acts. At no time did she lose insight, since she realized that her state of mind was pathologic.

Psychotherapy was attempted by a colleague of high standing, with no results. Drugs were used, mainly sedatives, together with amphetamine sulfate, hormones, vitamins and so forth, but the psychosis increased in severity despite these forms of treatment. Electric-shock treatment was finally decided on, and the patient had to be forced into taking it. Three shocks were given at her home. At the end of the third she begged to have the treatment stopped, stating that she felt much better and that the obsessive and grief-stricken thoughts were "far away." Her appeal was granted, and she steadily continued to improve. Mild sedatives were then sufficient to ward off sleep. Amphetamine sulfate was used as a cere the shoe months after following the onset of the was stopped.

The patient has continued to remain well. The grief reaction is still present but in a rational form. The obsessive and compulsive reactions have disappeared and she is in normal condition.

CASE 2. A 52-year-old, married woman with a previous history of moderately neurasthenic reactions had always been dependent on her husband for decisions of major importance and, entirely wrapped up in her domestic affairs. In June, 1939, her husband, a distinguished engineer, suddenly died of coronary thrombosis. On his death it was discovered that his affairs were in an extremely tangled state. He had been lavish in his help to others, but left no legal papers that indicated the amounts he had given nor the circumstances

under which the loans were to be repaid. Thus, the estate consisted of a small amount of insurance and a large amount of dubiously collectible loans and gifts.

of dubiously collectible loans to widows girls.

Almost immediately the widow plunged into a severe depressive reaction, and was constantly preoccupied with the injustice and ungratefulness of those who had been the objects of her husband's benevolence. Against her own will she had a bitter and disloyal resentment against her husband, partly because he had not taken her into his confidence, but mainly because of the carelessness with which he had kept his accounts. She became sleepless, lost weight, was constantly agitated over the situation, and reiterated her feelings of doubt and helplessness. She was unable to do her housework and could make no plans for the future. There were no delusions. As a matter of fact, whatever she stated about her husband's financial affairs was entirely true, since a survey of his accounts and his checkbooks showed an appalling lack of discretion in the way his money had flowed into the pockets of others.

of others. Psychotherapeutics, a change of scene, sedatives, hormones and finally a prolonged stay in an institution for the treatment of mental disease were equally unavailing, and after nearly four years the condition remained practically unchanged. Doubt, indecision, depression, agitation, impairment of the appetite and inability to sleep or to carry on her life in any co-ordinated, organized way were still present and continuously expressed, to the complete distraction of the patient, and the demoralization of her family.

On September 1, 1942, outpatient electric-shock treatment was begun, almost against the patient's will, since she could in no way decide what to do. Ten treatments were given in rapid succession. Little improvement was noted, and

even know she was a widow, and had no memory of the facts and names of people with whom she had been on intimate terms throughout her life, although she could recognize her son and a few closely related persons. She did not remember her illness, and the last five years of her life were practically wiped out. During the next 3 weeks gradually her memory returned. She recalled her husband's death, and commenced to recognize that she had been sick and to realize the nature of her abnormal response. Sleep became normal, and the appetite was restored in adequate measure; at the end of 6 weeks she recommenced her housework, and in the course of the next month she was reading newspapers, listening to the radio, visiting friends and carrying on her duties as mother and housekeeper about as well as ever before. She was greatly concerned about the money that had, as she put it, "disappeared into the pockets of others," but for the first time she was able to take intelligent and adequate measures for the recovery of the lost funds, and in fact showed considerable intelligence and business judgment in dealing with her affairs.

her affairs. She has reported from time to time during the year since the shock treatment was discontinued. Although she is still a neurasthenic type of person, complaining from time to time of various pains and aches, — digestive disturbances and the like, — she has maintained a well-organized mental life and is substantially well.

CASE 3. A 48-year-old, married woman carried on an active life in her community, was a musician, and was devoted to her husband and two children. The former was killed in an accident. The patient felt as though she had "no prop left" in her life. Immediately she fell into a state of depression, with self-accusation on the slender ground that she had not prevented her husband from working too hard and thus subjecting himself to unnecessary risks. She became entirely sleepless, lost her appetite completely, complained of burning feelings throughout her body, and manifested an inability to make decisions in any minor

*Professor emeritus of neurology, Tufts College Medical School; clinical professor of psychiatry, Harvard Medical School; director of research, Boston State Hospital.

[†]To my knowledge, this term was first used by Cobb and Lindemann.²

affairs. Finally she made a desperate attempt at suicide and was sent to a state institution, where she remained for a month. She was then discharged, against advice, with a diagnosis of reactive depression. During her stay she had been appalled by her incarceration and the manifestations of insanity by other patients. She sequestered herself in her home for nearly a year following her discharge. She had no desire for any of the pleasures of life — what I² have elsewhere called "anhedonia" — and felt that the world was unreal and without any worth and that living was an almost intolerable burden. She could not even summon up interest in the affairs of her sons, who were in the Army. This brooding state remained unaltered for months, and, as the patient phrased it, she had felt "like a ghost" ever since her husband died.

Finally, in January, 1943, outpatient electric-shock treatments were given, five in number on alternate days. The improvement was marked from the third shock on. At the end of the series the patient slept well, had regained her normal appetite, smiled and laughed naturally, and was willing to take up her affairs again. She went back to her music, became absorbed in the care of her house, corresponded affectionately with her sons, and in a short time was reacting entirely normally to the death of her husband and to her status as a widow.

CASE 4. A 28-year-old, married woman was first seen on May 27, 1943, 6 months after the onset of her illness. She was intelligent, keen, active and social minded. Owing to the shortage of maids, she had to stay home each night with her baby, frequently alone. On one occasion she left the infant for an hour to visit a friend, and came home to find that he had suffocated in his crib. The grief reaction was extreme and was immediately associated with bitter self-accusation. Nothing would console her. She finally came to Boston from a distant city and placed herself under the care of a group of distinguished psychiatrists, who utilized psychotherapy but without avail.

On May 28 and 30, I administered electric-shock therapy. When she recovered from the unconsciousness and stupor of the first treatment, she felt peaceful and said that she had not been in so desirable a state of mind for many months. At the end of the second shock she felt entirely well, and as a consequence no further treatments were administered.

She returned to her home and resumed her domestic duties.

DISCUSSION

Each of these cases, all of which significantly occurred in women, was characterized by an intense and prolonged grief reaction following a tragic bereavement. These reactions were to some degree warranted. The prolongation, intensity and transformation of the grief are its pathological features. All the patients fell into a vicious circle of nervous and mental disturbance from which it seemed impossible to rescue them by the ordinary therapeutic measures. Just how the electric-shock method operated in these cases is a theme for fertile speculation, without, however, any basis of established facts. In Case 2 the abnormal mental state had persisted for years, and it was necessary to produce an amentia — that is, to wipe out for a time almost all memory — before the personality could reorganize itself along normal lines. In the other 3 cases a few electric shocks brought about striking and immediate improvement and recovery. It does not therefore seem necessary to erase the memory of the traumatic experience to produce a readjustment to the altered life that bereavement has brought in its train. The value of shock treatment does not appear to have a psychologic foundation. Rather, physiologic alterations of an unknown type take place, and this is the basis of the recovery.

MEDICAL PROGRESS

CARDIOGENIC SHOCK (Concluded)*

NORMAN H. BOYER, M.D.†

BOSTON

ORIAS²⁸ studied the dynamic changes in the ventricles following experimental coronary occlusion and offered a reasonable, and probably important, explanation for the changes observed. In general, three types of responses were encountered. In a few animals the aortic and left-ventricular pressures fell progressively with evidence of cardiac dilatation and failure. In another group of animals there was an immediate fall in aortic and left-ventricular pressure, followed quickly by recovery of the cardiodynamics to the preligation level. A small group of animals showed no fall in pressure, and in them the only evidence of altered dynamics

was a decrease in the ejection phase, an alteration that was also observed in the other groups. Orias interpreted these responses as indicating that deletion of a portion of the ventricular muscle immediately resulted in a hypodynamic beat and consequent dilatation of the heart. If the nonischemic muscle was able to respond normally to the increased diastolic size, it compensated for the loss of the ischemic area and the dynamics returned to normal. If the nonischemic muscle could not respond with increased vigor of contraction, in accordance with Starling's law, progressive heart failure and a falling blood pressure appeared. This may well explain why a fall in blood pressure has not been a striking feature of experimental coronary occlusion, for in the majority of such experiments the blood supply and

†Assistant professor of medicine, Boston University School of Medicine; visiting physician, Evans Memorial, Massachusetts Memorial Hospitals (on leave of absence).

the cardiac reserve of the uninfarcted regions were essentially normal. Unfortunately, this does not obtain in many patients with coronary occlusion because of the presence of generalized coronary artery disease or because of the loss of cardiac reserve incident to chronic hypertension. Obviously, the amount of uninfarcted muscle remaining, as well as its condition, is an important factor in the ability of the heart to compensate. Thus the hope of compensation in a heart subject to depletion of a large portion of its muscle mass is slim.

Even if Orias's concept is fundamentally correct, — and no better one has yet been offered, — it is still conceivable that peripheral mechanisms play a contributory role. Two possibilities present themselves. First, primary or neurogenic shock may occur at the onset of the attack, and the resultant fall in blood pressure may so diminish blood flow in the unoccluded coronary arteries as to depress the uninfarcted muscle, thus preventing its normal compensatory response. The result would then be progressive hypodynamic heart action and shock persisting beyond the usual duration of primary shock. That such a train of events may occur cannot be gainsaid, but the force of the contention is somewhat weakened by the fact that in occasional cases the onset of the attack is marked by an increase in blood pressure that may later give way to shock. Such a series of events is unusual because the mere ability of the heart to sustain a blood pressure higher than preinfarction levels attests to its ability to compensate fully. In the rare cases in which it does occur, other collateral factors may possibly play a role.

The second possibility is concerned with whether true peripheral shock may not ultimately appear following a prolonged period of capillary anoxia secondary to cardiogenic shock. It is well known that large doses of epinephrine given over a long period of time may give rise to shock, and that intermittent obstruction to the arterial or venous blood flow to an extremity may do the same. Furthermore, it has recently been shown²⁹ that sustained hypotension induced by continuous stimulation of the carotid sinus may induce the clinical and pathologic picture of traumatic shock. Against such a contention is the fact that no significant decrease in circulating blood volume or hemoconcentration has been demonstrated in myocardial infarction accompanied by shock, although studies of this kind have not been correlated with the duration of the shock. A more potent argument against such a concept is the fact that the state of shock induced by prolonged anoxia is largely an irreversible process and that recovery is rare. This is not necessarily true in myocardial infarction, for patients may remain in shock for hours or even a day or two, yet ultimately recover.

It appears, therefore, that the bulk of evidence, both direct and theoretical, is overwhelmingly in

favor of the concept that shock in myocardial infarction is largely, and probably solely, a manifestation of heart failure.

Some therapeutic considerations can be adduced from the crystallization of present knowledge concerning shock in myocardial infarction. Since the evidence is opposed to any lack of circulating blood volume or loss of effective filling pressure of the left ventricle, measures adopted to combat traumatic shock, such as the use of intravenous fluids or blood, are not only uncalled for but are, of course, contraindicated. Conversely, the reduction of the circulating-blood volume is not contraindicated so long as the evidence indicates an adequate supply of blood to the left side of the heart. The combination of shock and pulmonary edema is not unusual, and in such cases there has been a reluctance to bleed the patient because of the possibility of aggravating the shock. Since pulmonary edema is a manifestation of high pressure in the pulmonary veins, it follows that more than adequate blood is available to the left side of the heart, and no hesitancy need be felt in venesecting such patients. Indeed, pulmonary edema may constitute a more immediate threat to life than does shock, and venesection may occasionally be lifesaving. Stead and Ebert³ withdrew 650 and 500 cc. of blood, respectively, from two patients with myocardial infarction and shock without any evident harmful effects.

Unless the reasoning has been false, measures designed to combat shock in myocardial infarction should be mainly directed toward supporting the uninfarcted muscle. Some attention has been given to the subject of treatment of this form of shock, but it has not received the consideration it deserves, probably owing to the contention of some clinicians that a low blood pressure relieves the work of the heart and therefore should not be vigorously combated. It should not be inferred that moderate reduction of blood pressure should be attacked vigorously, but it is hardly conceivable that a state of profound shock is helpful to the bodily economy.

The intravenous injection of 50 per cent glucose solution has been recommended by some authors for the treatment of shock in myocardial infarction, and success with this method has been reported. I have never seen recovery from shock attributable to this procedure, and many clinicians have had a similar experience. Furthermore, there is no evidence that the blood volume needs to be supplemented, nor is there evidence that the heart lacks fuel to burn — the two main attributes of hypertonic glucose solution.

Oxygen therapy has been found useful in the treatment of shock in myocardial infarction. The rationale of its use is not to increase the oxygen supply to the infarcted tissue, for it is probable that no available measure can immediately increase the blood or oxygen supply to this area.³⁰ Its usefulness

lies in increasing the oxygen available to the uninjured muscle, hence enhancing its ability to compensate. Even the small amounts of additional oxygen that can be taken up by normally saturated blood may serve a useful purpose. It is probable, however, that at times, owing to pulmonary congestion, the blood is not normally saturated. Under such circumstances, oxygen administration fulfills an important service.

The experimental work of Manning, McEachern and Hall³¹ and LeRoy and Snider³² indicates that sudden occlusion of one coronary branch leads to reflex constriction of other coronary arteries. If such a phenomenon occurs in human beings, it must constitute a significant barrier to an adequate response of the uninjured muscle. The drugs that have been recommended for overcoming this reflex constriction are atropine, aminophylline and papaverine. In addition, aminophylline is a myocardial stimulant and may be temporarily useful for this reason alone.^{33, 34} Also, papaverine has been found to decrease ventricular irritability,^{35, 36} and its use may reduce the danger of ventricular ectopic rhythm. None of these drugs have been adequately evaluated for their effect on shock in myocardial infarction, and their inclusion here is based on theoretical grounds alone.

If one accepts shock in myocardial infarction as a manifestation of heart failure, the use of digitalis and other cardiac glycosides must come in for very serious consideration. In general, the use of digitalis has been avoided during the acute stages of the disease, for the following reasons. First, it decreases cardiac output in patients without heart failure, and it has been thought that this effect may aggravate the shock. Since the evidence favors the presence of congestive heart failure in myocardial infarction, even in patients who show predominant signs of shock, it is apparent that this objection is insignificant and may be disregarded. Second, the use of digitalis has been objected to on the ground that stimulation of the heart may increase the danger of cardiac rupture. Undoubtedly this objection has been overrated, particularly so in the present connection since the appearance of shock is usually limited to the first day or two, a time when ventricular rupture is unlikely. Moreover, digitalis has commonly been used to combat congestive heart failure in the later stages of cardiac infarction, when rupture is more likely to occur, without evidence of undue prevalence of this complication. Finally, the objection has been raised that digitalis increases ventricular irritability and increases the likelihood of fatal ventricular fibrillation. Although this objection is possibly valid, it should be recalled that such ventricular irritability is usually to be attributed to excessive amounts of digitalis. It has not been demonstrated that cardiac infarction sensitizes the heart to therapeutic amounts of the drug.

It has been shown that in the experimental animal digitalis does not significantly alter the fibrillation threshold of the ventricles.³⁷ It has also been demonstrated that the spontaneous ventricular fibrillation that occurs with toxic amounts of digitalis differs in several particulars from that which occurs with coronary occlusion.^{37, 38} Although myocardial ischemia lowers the fibrillation threshold, it has not been shown that this increases the tendency of digitalis to produce fibrillation. Indeed, there is considerable evidence that this is not true.

In 1925, Gold³⁹ found that the lethal dose of ouabain for cats subjected to coronary artery ligation did not differ from that for normal animals. This study extended over a period of twenty-four hours following ligation. More recently, these findings were confirmed by Bellet, Johnston and Schecter,⁴⁰ but the latter authors extended the period of observation and found that four days following ligation the tolerance to digitalis diminished by 23 per cent of normal. Still later, Travell, Gold and Modell⁴¹ reported that the tolerance of cats to digitalis three weeks after ligation of the coronary arteries was diminished by 25 per cent. Since shock in cardiac infarction is usually an early manifestation, it appears from these experiments that no great fear need be felt in the use of digitalis. Furthermore, as emphasized by Travell, Gold and Modell, all these studies have been concerned with lethal amounts of the drug, and no information concerning therapeutic amounts of the drug has been forthcoming. They conclude that the results lend no support to the belief that the use of digitalis is attended by any special hazards in these cases [coronary occlusion].

Certainly digitalis has been used in many patients with acute myocardial infarction accompanied by congestive heart failure. The number of sudden deaths in such patients is probably no larger than might be expected in a similar group not receiving digitalis. Stead and Ebert⁵ gave intravenous strophanthin to 2 patients in shock with myocardial infarction without evidence of benefit or harm. The number is, of course, too small to evaluate the possible hazards or benefits of this drug, but it indicates that digitalis bodies can be given under such circumstances without invariably producing disastrous results.

Strophanthin or ouabain is probably the drug of choice, since its action is rapid, it does not accumulate so readily as digitalis, and it is said to have a greater direct action on the myocardium than does digitalis.⁴²

It should not be supposed that digitalis bodies are being enthusiastically recommended for the treatment of shock in myocardial infarction. There is no assurance that they do good nor that they are entirely free of danger. The suggestion is simply made that, on theoretical grounds, such substances

may be expected to turn the scales in some cases, and that objections to their use have probably been greatly overemphasized.

The subject of therapy should not be left without some discussion of the use of pressor drugs. A few physicians have used epinephrine unhesitatingly in shock associated with myocardial infarction, some have been goaded into its use by the necessity of desperate circumstances, and some have avoided it completely. Several objections have been raised to its use. It has been thought to be contraindicated in all forms of shock because arteriolar constriction is already present, and if epinephrine does succeed in producing further constriction it will only serve to increase capillary anoxia and thus aggravate the shock. This may apply to traumatic shock, but it is probably insignificant in the type of shock under discussion.

Pressor drugs have also been objected to on the ground that hypotension relieves the work of the heart and is a compensatory mechanism, and hence should not be combated. This is not an especially appealing argument. Inasmuch as the ability of the uninfarcted muscle to compensate is determined, in large part, by its blood supply, which, in turn, is determined largely by the aortic blood pressure, it seems desirable to overcome a profound fall in blood pressure if possible. The opposing argument could only be considered valid if it could be shown that the decrease in cardiac work associated with shock is disproportionately greater than the decrease in coronary blood flow. This seems extremely unlikely.

Epinephrine has also been objected to on the ground that it tends to produce ventricular irritability. This belief has some support in clinical and experimental observations, but recent work indicates that the ventricles of experimental animals are more resistant to the production of ventricular fibrillation after the administration of epinephrine than they are in the untreated state.³⁸ It should also be recalled that in patients with Adams-Stokes's attacks complicating acute myocardial infarction, epinephrine has been used repeatedly and in large amounts with nothing but benefit resulting in the majority of cases.

Nieck⁴ has recently reviewed the evidence relative to the production of ventricular tachycardia by epinephrine, especially in regard to its effect during cyclopropane, chloroform and ether anesthesia. Several interesting observations pertinent to the present discussion have been made. Under the conditions of the reported experiments, it was demonstrated that, especially with cyclopropane, epinephrine produced ventricular tachycardia regularly, whereas similar doses in the unanesthetized dog produced it but rarely. It was also demonstrated that sensitization of the heart itself by cyclopropane is of much less importance than nervous impulses reaching the heart by way of the sympathetic pathways. It is possible, therefore, that the combined

effect of cyclopropane and epinephrine is simply equivalent to the effect of a large dose of epinephrine alone. In any event, the analogy of sensitization of the heart by anesthetic agents and the possible sensitization by coronary occlusion may not be very close, and is certainly not established. Nieck also noted that other amines were as effective as adrenalin in producing ventricular tachycardia under cyclopropane anesthesia, and that only amines with a catechol ring had this ability. To be effective, the various side chains in the structural formula must be attached to the 3-4-dihydroxy ring. Other drugs capable of producing the same degree of blood pressure increase but without the characteristic structural formula did not induce ventricular tachycardia. Such drugs were Ephedrine, Amphetamine (Benzedrine), Paredrine, Synephrine and Neo-Synephrine. It seems, therefore, that if pressor substances are to be used in myocardial infarction, one of the latter group is preferable to epinephrine.

A more important objection to epinephrine is its tendency to increase both the general and the cardiac metabolism. This effect is doubtlessly out of proportion to the increase in blood flow incident to its use, and the administration of epinephrine is therefore an uneconomical and probably unsafe procedure.⁴⁴ Ephedrine is an equally good, if not a better, pressor drug, and its tendency to stimulate metabolism is somewhat less than that of epinephrine.⁴⁵ Hence it is superior to epinephrine on at least two counts and perhaps deserves a place in the management of shock with myocardial infarction. Some of the newer sympathomimetic amines may prove to be superior, for one reason or another, to ephedrine.

* * *

It is fully realized that certain of the ideas expressed in this section devoted to myocardial infarction will be new to many readers and perhaps unacceptable to some. The ideas relating to treatment, especially, are not expressed as established facts, but an attempt has been made to assemble recent developments and to indicate the need for critical re-examination of older beliefs. It should again be emphasized that many questions are still unanswered, and that until more information is available on controversial points, trial of the unorthodox procedures should properly be limited to gravely ill patients whose prognosis has heretofore been almost universally bad. It should also be emphasized that, irrespective of the soundness of these therapeutic suggestions, many such cases are hopeless from the beginning because of the large size of the cardiac infarct and the paucity of remaining uninfarcted muscle.

CASE 30091

PRESENTATION OF CASE

A sixty-five-year-old man was admitted to the hospital with a compound fracture of the right leg incurred a few hours previously after a fall down a flight of stairs.

For about ten years prior to admission the patient had been treated in the Out Patient Department for pernicious anemia with parenteral liver extract. In spite of this therapy the hemoglobin and red-cell count had been falling over a period of a year. He had occasionally noted paresthesia in his feet and muscle cramp, with some difficulty in walking. He had dyspnea on exertion. His diet was poor, and he had been drinking 6 to 10 glasses of beer daily for many years. For three years the liver had been palpable.

Physical examination revealed a well-developed, well-nourished man who appeared drowsy. The tongue was red and beefy. A few rhonchi were audible at the right base. The heart was negative. The liver edge was palpable 3 cm. below the right costal margin. The left ankle jerk was absent, but the vibration and position senses seemed intact. The right leg revealed a compound comminuted fracture of the right tibia and fibula.

The temperature was 99.4°F., the pulse 132, and the respirations 16. The blood pressure was 160 systolic, 95 diastolic.

Examination of the blood showed a red-cell count of 3,920,000, with 65 per cent hemoglobin. The white-cell count was 8800, with 80 per cent neutrophils. There were no red-cell abnormalities. A urine examination was negative. The van den Bergh, blood nonprotein nitrogen, and blood protein determinations were normal. The albumin-globulin ratio was 3.0. The prothrombin time was 35 seconds (normal, 22 seconds). A blood Hinton test was negative.

The patient was immediately taken to the operating room, where a débridement, irrigation, open reduction and application of a Lane plate to the tibia were performed. A cast was applied and the patient was transfused and given sulfadiazine, which was discontinued after four days because of a fall in the white count to 4400. The temperature rose to 101

or 102°F. following the operation. An x-ray film of the chest during this period revealed prominence of the lung markings, especially at the right base. On the third postoperative day the temperature became normal, and remained so for two weeks, during which time the patient was asymptomatic. On the eighteenth hospital day, following a transfusion, the patient had a chill with a rise in temperature to 101°F., which continued for several days. The patient felt tired, and his appetite was poor. There was questionable tenderness over the left kidney, but the urine was negative. The lungs were clear. Two days later the cast was removed. The wound was well healed except for a small area over the fracture site, from which serosanguineous fluid exuded. This area soon sloughed, leaving a small portion of the plate exposed, but there was no evidence of extending infection.

Following a few days of normal temperature, it again rose, going to 100 or 101°F. daily. The patient remained lethargic. His appetite was poor, and he complained of cramplike abdominal pain and malaise. There was soreness in the epigastrium to the right of the midline. He also developed tenderness of the right calf, associated with edema of the foot, and a bilateral femoral-vein ligation was subsequently performed, without apparent change in his condition.

Although microscopical examination of the urine was essentially negative, urine culture revealed a moderate number of colonies of *Staphylococcus albus*. Because of this, together with the persistently elevated temperature, the patient was given small doses of sulfathiazole for a period of about two weeks, during which time there were only occasional rises in temperature to 100°F. The white-cell count ranged from 4000 to 7000, with 49 to 76 per cent neutrophils. Because of inadequate caloric intake and increasing evidences of dehydration and malnutrition, large amounts of vitamins as well as parenteral fluid and glucose were given. Administration of vitamin K (Hykinone) parenterally did not bring down the prothrombin time, which eventually reached 52 seconds (normal, 22 seconds). The blood protein was 8.9 gm. per 100 cc., with an albumin-globulin ratio of 0.5. The van den Bergh test remained normal. A cephalin flocculation test was +, but later ++. A bromsulfalein test revealed 35 per cent retention of the dye. Blood cultures were negative.

The patient's condition gradually deteriorated. The temperature spiked to 103 and 104°F. daily, and he had several chills. Examination revealed an emaciated man with a Parkinsonian rigidity and masklike facies. Crackling rales were audible at both bases, being more marked on the left. The heart was slightly enlarged, with soft systolic murmurs at the base and apex and an early diastolic apical gallop rhythm. The blood pressure was 103 systolic, 68 diastolic. The liver and the tip of the

*On leave of absence.

spleen were palpable. Some brawny ankle edema was present. A portable roentgenogram of the chest revealed poorly outlined mottled areas of increased density scattered throughout both lung fields.

On the seventy-second hospital day the patient developed considerable respiratory distress and became totally disoriented. He was placed in an oxygen tent but expired two days later.

DIFFERENTIAL DIAGNOSIS

DR. JACOB LERMAN: There are several interesting points that we should review and comment on before discussing the diagnosis. This man apparently had adequate parenteral therapy for pernicious anemia and then began to lose ground. Usually one of several factors explains the failure to respond or the tendency to relapse. Either the therapy is inadequate or subminimal, so that gradually the patient slips into a relapse, or infection or some toxic agent supervenes, or another degenerative disease develops. In this particular patient several factors existed. His diet was poor, he had been taking alcohol, and he had signs suggesting liver damage. All three factors might play a role in the failure to maintain a good response or in a tendency to relapse. The tendency to relapse is confirmed by the fact that he had a red, beefy tongue and weakness. Although there is a suggestion that he might have had combined-system disease, the presence of vibration and position senses is strongly against that possibility. The blood picture is that of mild anemia — he had not maintained his normal red count and hemoglobin. The increased prothrombin time is further evidence of liver damage. It is true that such an increase can be due to inadequate intake of vitamin K, but we learn later that vitamin K administration did not help.

The patient was operated on, and given sulfadiazine until leukopenia developed. On the eighteenth postoperative day there was a transfusion reaction. This raises the question whether the reaction could have been due to antibodies against the Rh factor. It is possible but one hardly expects a reaction to the Rh factor on the second transfusion, since it usually takes several transfusions to produce such a reaction.

There is a note that the patient was beginning to have renal pain. We know that in pernicious anemia, particularly in those cases associated with combined-system disease, kidney infection is of common occurrence. So our attention is drawn to the possibility of pyelitis, pyelonephritis or abscess involving the kidney or perirenal tissues. Further evidence of urinary infection is offered by the positive urine culture. The service apparently gave sulfonamides in an attempt to reduce the infection; it was partly successful but did not result in a cure.

The fever, lethargy, abdominal cramps and fullness in the epigastrium point toward the gall bladder

as the locus of infection. Again, gall-bladder disease is common in pernicious anemia. In addition one must pay attention to two other places as loci of infection — namely, the fracture site and the thrombophlebitis in the right leg. Inasmuch as femoral-vein ligation did not do much good, it seems that the infection was not localized in the veins of the leg.

There is additional evidence of liver disease — namely, failure to respond to vitamin K, a high serum protein (so common in the early stages of liver disease), reversal of the albumin-globulin ratio, a positive cephalin flocculation test and, finally, retention of bromsulfalein. Later on there is evidence that he was developing cardiac failure — namely, rales at the bases, an enlarging heart, diastolic gallop rhythm, a drop in blood pressure and edema of the ankles. Certainly he must have had some underlying arteriosclerotic heart disease that was made worse by the prolonged fever.

What about the diagnosis? I think we have to consider several diagnoses in this case. Since he had treatment I doubt that we can prove the presence of pernicious anemia, and I believe that the pathologist will also be unable to make this diagnosis. The patient undoubtedly had cirrhosis in the early stage which was made worse by infection or by drugs. He had sulfonamides twice, and in the presence of liver disease they can cause additional damage. It is possible that he never had pernicious anemia, because in cirrhosis there frequently exists a hyperchromic anemia that can be mistaken for pernicious anemia. Since this anemia also responds to liver, there is a way of distinguishing one from the other after treatment. Undoubtedly he had arteriosclerotic heart disease with congestive failure.

The important problem is to determine the cause of the prolonged fever. A patient with cirrhosis may have superimposed hepatitis, which can give a prolonged spiking fever. If this were the case, the patient would have had jaundice. Since there is no mention of jaundice we can rule out hepatitis superimposed on cirrhosis.

Malignant disease in various locations might produce prolonged fever. Could this fracture have been a pathologic fracture? I can find no clue in the record that it was. Hepatoma, which sometimes supervenes in cirrhosis, can be the cause of fever. Carcinoma of the stomach should be mentioned since it is frequently associated with pernicious anemia. The patient certainly had not had carcinoma of the stomach for ten years. He could have had polyps of the stomach that had undergone malignant degeneration. There is, however, no evidence for this diagnosis; I merely mention it. Lymphoma should always be mentioned, particularly the type located in inaccessible regions, such as the retroperitoneal lymph nodes. Multiple myeloma is suggested by the high serum protein, but that is the only evidence we find for such a diagnosis.

Could there have been any sepsis coming from the wound itself? Although the statement is made that "there was no evidence of extending infection," there was enough to produce thrombophlebitis. Other types of infection should be considered, such as generalized or miliary tuberculosis. I merely mention them, but find no evidence for them. The same is true for subacute or chronic endocarditis, and for certain types of noninfectious diseases, such as periarteritis nodosa and lupus erythematosus disseminata, any one of which may cause prolonged fever.

I should like to see the films of the lungs.

DR. LAURENCE L. ROBBINS: These films demonstrate the fracture, but I do not believe that we need to spend time on them. I do not see anything that suggests a pathologic fracture.

These two films of the chest were taken one month apart while the patient was in the hospital. This portable film was taken during the last acute episode. About the only thing I can see of significance is the diffuse increase in the markings throughout the lungs, which could have been on the basis of increase in size of the vascular or lymphatic channels. The ribs do not suggest myeloma. Terminally there are areas of density. I am not sure of their significance because the film was taken with a portable machine and there was motion; however, one would have to consider multiple small infarcts. From the abdominal film one can say that the spleen was certainly enlarged. There is an indefinite shadow of calcification overlying the left kidney, which is possibly outside the kidney. The bones of the lumbar spine and pelvis show no degenerative changes or evidence of multiple myeloma.

DR. LERMAN: There are two places where the evidence points to the presence of infection. One is the kidney pelvis, the substance of the kidney or the tissues around the kidney. Such an infection, with resulting thrombophlebitis, could have accounted for pulmonary emboli. The other locus of infection is the gall bladder. There were, however, no localizing signs in the region of the gall bladder. Another possibility is repeated emboli from the thrombosed femoral vein. Although this is unlikely because of the bilateral femoral-vein ligation, there is a possibility that the thrombus extended beyond the point of ligation, continued to throw off emboli and thus produced pulmonary infarcts. In any case the x-ray findings may be explained either by repeated pulmonary infarcts or by terminal bronchopneumonia. They certainly do not suggest metastases.

I shall have to conclude that this patient had an infection either in the kidney or in the gall bladder, or in both, but I do not know what type of infection.

DR. J. H. MEANS: I thought the chills were impressive. I wondered if he could have had a staphylococcal pyemia, with abscesses in the kidney, liver and elsewhere. The negative blood cultures do not rule out the diagnosis.

DR. FLETCHER H. COLBY: Where was the primary focus?

DR. MEANS: I do not know.

DR. JAMES B. AYER: You did not say anything about the Parkinsonian feature. Does it fit in?

DR. LERMAN: No, except for the fact that the patient was very sick.

CLINICAL DIAGNOSES

Pyelonephritis.

Hepatitis.

Bronchopneumonia.

DR. LERMAN'S DIAGNOSES

Renal infection (? type)?

Cholecystitis?

Portal cirrhosis.

Arteriosclerotic heart disease.

Pulmonary infarction.

ANATOMICAL DIAGNOSES

Pulmonary tuberculosis.

Miliary tuberculosis of liver, spleen, kidney, and bone marrow.

Portal cirrhosis of liver.

Mycotic aneurysm of sinus of Valsalva (tuberculous).

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: This man was a puzzle on the surgical ward, and the surgeons called in the medical men frequently to see if they could find out the cause of the prolonged fever. The surgeons believed that the cause of the fever had nothing to do with the fracture.

At autopsy, we found both lungs expanded and almost completely solid. On section, numerous small cavities that looked like broken-down abscesses were seen. It was thought that the disease was a diffuse bronchopneumonia with secondary abscess formation. Another interesting finding was in the aorta. Just above the aortic valve there was a tear in the intima with the formation of an aneurysm into the sinus of Valsalva. The aneurysm measured 3 cm. in diameter and had not ruptured.

Microscopic examination of the lung showed that this man had an acute diffuse tuberculous process throughout the lungs — a tuberculous pneumonia. He also had miliary tuberculosis of the kidneys, liver and spleen. The aneurysm in the aorta proved to be a mycotic aneurysm due to tuberculosis, a very unusual occurrence. In addition to miliary tuberculosis, the liver showed evidence of an old portal cirrhosis. We were unable to find any evidence of pernicious anemia as Dr. Lerman predicted; there were large amounts of hemosiderin in the marrow spaces, as well as miliary tubercles, but no evidence of red-cell hyperplasia.

DR. COLBY: I was not here for the first part of this discussion, but it is interesting that, although the history states that the urine was negative, the patient had renal tuberculosis. In my experience in the past ten years I have never seen a case of renal tuberculosis that did not show albumin in the urine.

DR. CASTLEMAN: This was miliary tuberculosis, which I judge developed in the kidneys during the last two months of his stay. It was not a primary renal tuberculosis.

DR. LERMAN: Was there any evidence of recent hepatic disease?

DR. CASTLEMAN: No, with the exception of the tuberculosis.

CASE 30092

PRESENTATION OF CASE

A fifty-nine-year-old unemployed painter entered the hospital because of anorexia.

The patient had never been a "big eater." About five months before entry, however, he gradually lost his appetite so that he eventually ate "almost nothing." For a few weeks before entry his daily diet had consisted entirely of an éclair and one or two glasses of milk. Two months before admission he began to have a sensation of generalized abdominal pressure, which occurred two or three times daily, lasted one hour and was most severe in the morning. Two weeks prior to entry he began to have a strange, sharp precordial pain every two hours; this lasted five or ten minutes, and was relieved by eating and eructation and to a lesser degree by alkalies. He became progressively weaker, and for the week preceding entry had been so shaky that he fell when walking. He had been constipated for months, having had only two bowel movements weekly. The last bowel movement was one week before admission, at which time he thought that he recognized food eaten in the morning. He had had no abdominal pain, nausea, vomiting, hematemesis, melena, fever, chills or urinary symptoms. He had lost 40 pounds of weight since the onset of his illness.

Physical examination showed a pale, emaciated man who looked older than his stated age. Examination of the heart and lungs was negative. The abdomen was scaphoid. There were no masses, tenderness or spasm. The liver and spleen were not palpable. The lower poles of the kidneys were palpable. The cecum and sigmoid were felt and appeared normal. Rectal examination was negative.

The blood pressure was 135 systolic, 56 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a white-cell count of 19,100, with 76 per cent neutrophils. The hemoglobin was 8 gm. The urine was negative. The stools were guaiac negative. The blood protein was 4.8 gm. per 100 cc. A blood Hinton test was negative.

A gastrointestinal series showed a normal esophagus. The fundus of the stomach was not well visualized. A small amount of barium appeared to pass backward into the fundus, but the upper portion seemed to be filled by a rather smoothly demarcated mass. Within the mass there was a peculiar round air shadow, but that portion could not be filled with barium. A localized bulge of the diaphragm was seen in the region of the mass. Study of this area, however, was difficult because of the patient's emphysema. The remainder of the stomach and the duodenal cap were not remarkable. In about two and a half hours barium was seen in the transverse colon.

A gastroscopy on the twelfth hospital day showed the mucosa of the body of the stomach to be somewhat pale but not definitely atrophic. Close to the cardiac orifice, and extending into it, was a rather smooth, rounded mass measuring 5 cm. in diameter; there was no evidence of ulceration.

The patient was given two transfusions of 500 cc of blood each, and an operation was performed on the thirteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD HAMLIN, JR.: I think it is fair to say that the abnormal laboratory findings were due to cachexia. The patient had eaten nothing but éclair for a long time, and there is no reason why he should not be anemic, and have a low blood protein as well. On the other hand, he may have had loss of blood. Since Dr. Benedict is here, I wonder if he could enlarge on the gastroscopic examination.

DR. EDWARD B. BENEDICT: I said that no ulceration was "visible." I could not see around the tumor. Furthermore, I said that there was a blood clot hanging from the lower margin of the tumor.

DR. HAMLIN: That is of considerable interest. I tried to imagine a gastric tumor without ulceration and with air in the center, and that led me to wonder whether a lipoma could show increased radiance that might be mistaken for air. Dr. Benedict's visualization of a hanging blood clot makes that extreme unlikely.

DR. LAURENCE L. ROBBINS: This spot film perhaps shows the lesion to the best advantage. Normally, we should expect to see the fundus of the stomach extending backward in this region. Here we find a relatively smooth mass that apparently fills the greater portion of the fundus. Incidentally, this is a place that is particularly difficult for a gastroscopist to see. The air shadow is present on several films, but at no time were we able to get any barium into it. The statement is made in the record that the examination of the area was difficult because of emphysema. That is simply because this area is beyond the reach of palpation, and to determine the changes we like to make use of the diaphragm. This patient had so much emphysema that the diaphragm

did not move well, and the examination was difficult, but I think that there was a tumor.

DR. HAMLIN: From an academic point of view is there increased radiance in lipoma of the stomach?

DR. ROBBINS: I have never seen one, but I think there should be if lipomatous tissue is surrounded by barium or by tissue with the density of water, such as mucous membrane, muscle and so forth.

DR. HAMLIN: I must try to determine what type of gastric tumor this was. It obviously does not seem to have been a typical carcinoma of the stomach because of its location and also because of its appear-

case, although we did not give much weight to either diagnosis because of the absence of any real evidence of bleeding except microscopically. In my experience many of the patients with leiomyosarcoma have had massive hemorrhage.

A transthoracic incision was made. As soon as the diaphragm was visualized it was obvious that we were dealing with a carcinoma that had invaded a large portion of the central tendon of the diaphragm. A free portion of the diaphragm near the costal margin was incised and the abdomen opened. A massive tumor arising in the stomach and invading the spleen and

FIGURE 1. Cross Section of the Tumor Mass, Showing Extension from the Stomach into the Spleen.

ance by x-ray and by gastroscopy. Was it malignant or was it one of the rare benign forms of tumor? Statistically, it is more likely to have been malignant. Furthermore, the fairly short history and the age of the patient suggest a malignant tumor.

I am not going to go through the various types of tumor that can be found in the stomach. Leiomyoma, fibromyoma and sarcoma are the most likely ones in that portion of the stomach under these circumstances. The fact that an air shadow was present indicates in all probability a small fistulous tract from the center of the tumor to the interior of the stomach and, as Dr. Allen has pointed out on occasions, that is almost pathognomonic of the leiomyosarcomatous type of lesion. I shall leave it at that.

DR. RICHARD H. SWEET: We considered lymphoma and leiomyosarcoma as possible diagnoses in this

the tail of the pancreas was found. At first it seemed almost impossible to remove this growth because of its invasion of diaphragm, spleen and pancreas, but it was finally decided that an attempt was worth while. As a result we completed the operation successfully, after having resected a large portion of the stomach with a piece of the diaphragm attached, the spleen, the left adrenal gland and about half the pancreas. Restoration of continuity was carried out by performing an esophagogastric anastomosis. The patient made a good recovery and has since left the hospital.

CLINICAL DIAGNOSIS

Carcinoma of stomach.

DR. HAMLIN'S DIAGNOSIS

Leiomyosarcoma of stomach.

ANATOMICAL DIAGNOSIS

Adenocarcinoma of stomach, with extension into spleen, pancreas and diaphragm.

PATHOLOGICAL DISCUSSION

DR. RONALD C. SNIFFEN: As Dr. Sweet has indicated, the description of this specimen is like a summary of the abdominal cavity in *Gray's Anatomy*. A 2-cm. segment of the esophagus was resected, a portion of the stomach and pancreas, the spleen, the left adrenal gland and a section of diaphragm.

The tumor lay high on the left wall of the stomach and was approximately 4 cm. in diameter, rather nodular; in its center there was a wide crater. This crater penetrated the tumor and led into the spleen (Fig. 1), which was adherent to the stomach and almost entirely replaced by tumor. In addition the neoplasm had invaded the pancreas, surrounded the adrenal gland and had invaded itself on the diaphragm.

Microscopically it was a Grade II adenocarcinoma that had arisen from the gastric mucosa.

COMPULSORY HEALTH INSURANCE

Two articles appearing elsewhere in this issue of the *Journal* deserve careful and thoughtful reading. In one, Mr. I. S. Falk, director of the Bureau of Research and Statistics, Social Security Board, clearly and simply outlines the principles and philosophies that have been responsible for the Wagner-Murray-Dingell Bill. In the other, Dr. Nathaniel W. Faxon, director of the Massachusetts General Hospital, discusses the pros and cons of compulsory health insurance, and makes an appeal for the utilization of existing agencies for the provision of medical care if compulsory insurance is judged to be necessary.

In spite of the remarkable advances of American medicine, there is no doubt that many people of this

country either lack facilities for medical care or receive poor medical care; on the other hand, the number is undoubtedly lower than that claimed by the groups that favor a radical change. The fact that, by and large, the mortality rates for specific diseases are as low in the United States as in any other country of the world is no guarantee that medical and hospital practice is perfect. As previously commented on editorially,¹ the health of the Nation is largely influenced by many nonmedical factors—decent wages, a high standard of living, unsurpassed educational facilities, excellent means of transportation and well-endowed and well-administered charitable organizations. To disregard these influences and to argue that medical and hospital practice is beyond criticism is plain stupidity, and one of the reasons why the attitude of many physicians and professional organizations toward the problems of medical care has received little sympathy from certain laymen and physicians who are more keenly aware of the actual state of affairs. On the other hand, there seems to be little excuse for radical experimentation, with the adoption of an entirely different scheme of medical and hospital practice. As aptly stated in *Hospital Progress*,² "Has the present system proved so inefficient, so hopelessly useless, so economically unsound, so professionally barren, as to make it necessary, if we must remedy the alleged shortcomings of our present system, to appeal to an incredibly different pattern of medical care?"

Every effort should be made to improve the health of the Nation, but the present system of medical and hospital care need not be discarded to accomplish this ideal. The process should be one of evolution, not one of dissolution. Organizations offering voluntary insurance have traveled far in the last five or ten years, and those under the control of physicians and hospital administrators assure a quality of service that can never be duplicated by a scheme in which bureaucracy and politics play essential roles. Certainly, the principles embodied in the letter sent to all congressmen from New England by their respective medical societies³ deserve careful consideration. If compulsory insurance ever becomes necessary, it should be at the state level, since conditions in different parts of the country are so vari-

ANATOMICAL DIAGNOSIS

Adenocarcinoma of stomach, with extension into spleen, pancreas and diaphragm.

PATHOLOGICAL DISCUSSION

DR. RONALD C. SNIFFEN: As Dr. Sweet has indicated, the description of this specimen is like a summary of the abdominal cavity in *Gray's Anatomy*. A 2-cm. segment of the esophagus was resected, a portion of the stomach and pancreas, the spleen, the left adrenal gland and a section of diaphragm.

The tumor lay high on the left wall of the stomach and was approximately 4 cm. in diameter and rather nodular; in its center there was a wide crater. This crater penetrated the tumor and led directly into the spleen (Fig. 1), which was adherent to the stomach and almost entirely replaced by tumor. In addition the neoplasm had invaded the pancreas, had surrounded the adrenal gland and had implanted itself on the diaphragm.

Microscopically it was a Grade II adenocarcinoma that had arisen from the gastric mucosa.

OBITUARY

ROY DENNIS HALLORAN

1894-1943

The death of Roy Dennis Halloran has taken from the neuropsychiatric section of the medical profession of this state and of the country an eminently capable man in the most productive period of his life. His death is a great loss for this state in particular, for he had contributed much in broadening the ideas on the hospital care and treatment of those who are mentally ill. No doubt were he to have lived and to have resumed his professional activities in Massachusetts, a great deal more could have been expected from him.

Dr. Halloran was born in Cambridge, Massachusetts, on August 4, 1894. He received his secondary education in the Boys' High School, Brooklyn, New York, and his A.B. degree *cum laude* from Dartmouth College in 1917. He received his M.D. degree from the College of Physicians and Surgeons, Columbia University, in 1920. After two years' internship in the Newark City Hospital he entered the field of psychiatry and became assistant physician and then senior physician at the Boston State Hospital. In 1928, he was appointed assistant superintendent of that hospital, where he combined clinical psychiatric work with research. Under guidance of Dr. James V. May, then superintendent of the Boston State Hospital, he developed into a capable clinical psychiatrist and an efficient administrator. From 1925 to 1933, he actively participated in research work carried at the Research Department of that hospital, under the guidance of Dr. Abraham Myerson, with whom he published several important papers. Their technic for obtaining blood from the internal jugular vein and internal carotid artery was a particularly outstanding contribution, for it offered a new method for the study of cerebral metabolism in nervous and mental diseases. This method became widely known and served as a basis of important contributions in this country and abroad. In 1929 he was appointed assistant to the Commissioner of Mental Diseases, and in 1933 became the first superintendent of the Metropolitan State Hospital, then in the process of construction and organization. During the nine years of his superintendentship he not only applied to this institution the high standards of psychiatric hospital administration for which our state has a long-standing and countrywide reputation, but with courage and energy broadened the functions of the state psychiatric hospital as a center of research and teaching in the care and treatment of the mentally ill. Thus, he designed and developed at the hospital the Medical and Surgical Centre of 400 beds as a complete general-hospital unit, which was approved by the American College of Surgeons in 1936. This was the first medical and surgical unit of a state psychiatric hospital to be approved in New England.

He developed a patients' library as a special department under a trained librarian, not merely as a diversional facility but as a part of the program of psychotherapy, the reading material being selected in accordance with the special psychologic requirements of each patient. He made special efforts to break the wall of psychologic and social isolation of the patients under prolonged treatment at the hospital. The theatricals and garden parties, and the exhibits of the patients' paintings, carvings and crafts held annually at the Metropolitan State Hospital, were favorably noted by the general press. He possessed outstanding abilities as a team builder and maintained high standards of morale and interest among the staff and employees of the hospital. In 1936, under the impetus of the establishment of the American Board of Neurology and Psychiatry for the certification of specialty, he organized post-graduate seminars in this branch of medicine. These have been held annually ever since and close to four hundred physicians—members of the staffs of psychiatric state hospitals and practitioners in Massachusetts and the adjoining New England states—have availed themselves of this educational opportunity. The seminars showed in a practical way how the teaching facilities of a state hospital can be effectively integrated with the teaching programs of university centers and medical schools to the advantage of large groups of physicians and students. Under his direction, the lectures of the seventh seminar, held during the fall and winter of 1941-1942, were transcribed and published in three volumes, each covering the lectures of one of the three semesters: "Military Neuropsychiatry," "General Psychiatry" and "General Neurology." The *Collected Lectures*, privately published at the Metropolitan State Hospital, have become widely known and are in great demand by young members of the profession, especially those who are in military service. He himself contributed much as a lecturer on administrative and clinical psychiatry at the seminars and as professor of clinical psychiatry at Tufts College Medical School.

In August, 1942, Dr. Halloran was called to take charge of the Neuropsychiatry Branch of the Office of the Surgeon General, being commissioned as a colonel in the Army of the United States. He accepted this call as a matter of duty to his country but hoped to return to the Metropolitan State Hospital after the war and to continue the work that he loved so much. While in Washington, he performed the difficult task of organizing the neuropsychiatric service of the Army during mobilization on an unprecedented scale. To his duties in military service, as usual, he gave all of himself. He died of a coronary occlusion on November 10, 1943, and was buried in the Arlington National Cemetery.

Dr. Halloran was a member of the American Medical Association, a fellow of the American Psychiatric Association and a member of the Amer-

ican Hospital Association. He was president of the New England Society of Psychiatry in 1940-1941, and president of the Massachusetts Occupational Therapy Association for two terms, 1939-1940 and 1940-1941. In 1938, he was representative from New England at the Conference on Behavior Problems of School Children in Washington, D. C. In 1939, he was a delegate of the Department of Mental Health at the American Psychiatric Convention. In 1940, he was member of a civil-service panel for the selection of a hospital superintendent in Rhode Island. He was a member of the Dartmouth Alumni Association and the University Club of Boston, as well as president of the Belmont Rotary Club in 1940-1941. He belonged to Sigma Phi Epsilon, Alpha Kappa and Gamma Alpha fraternities.

P. I. Y.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BARRY — Thomas A. Barry, M.D., formerly of Boston, died August 4, 1943, in the service of his country. He was in his thirty-fifth year.

Dr. Barry received his degree from Tufts College Medical School in 1936. He was a member of the Massachusetts Medical Society and the American Medical Association.

His mother survives.

CLARKE — Willis E. Clarke, M.D., of West Somerville, died February 23. He was in his fifty-seventh year.

Dr. Clarke received his degree from Tufts College Medical School in 1912. He was on the staff of the Cambridge City Hospital and Tufts College Medical School and was a lecturer for many years at the Boston Dispensary. Dr. Clarke specialized in diseases of the ear, nose and throat. He was a member of the Massachusetts Medical Society and the American Medical Association.

Two brothers and a sister survive.

SPELLISSY — Frank T. Spellissy, M.D., of Marlborough, died February 4. He was in his forty-ninth year.

Dr. Spellissy received his degree from Tufts College Medical School in 1919. He was a member of the staff of the Marlborough Hospital and a member of the Massachusetts Medical Society and the American Medical Association.

Two brothers survive.

WAR ACTIVITIES

INDUSTRIAL HYGIENE

"FUMES FELL 38 WORKERS"

Such were the headlines in all the Boston papers on December 11, 1943, when, according to the newspaper accounts, 38 women employed at a Cambridge plant had fallen unconscious from a mysterious gas.

Investigation by members of the staff of the Massachusetts Division of Occupational Hygiene revealed that the "mysterious gas" was carbon monoxide and that, of the 38 workers affected, only 8 required hospitalization for a single night. There were no fatalities or apparent sequelae. Atmospheric contamination with carbon monoxide occurred from the use of two brazing furnaces and a combustion chamber in which illuminating gas was reduced to a mixture of carbon dioxide 8 per cent, carbon monoxide 12 per cent, and nitrogen 80 per cent. A leak was found around the sight glass of the combustion chamber, but the primary cause of the poisonings was the breakdown of a ventilating fan.

The plant was immediately shut down, and the furnaces were run experimentally at night. Within one hour, concen-

trations in excess of 100 p.p.m. were found with a temporary 16-inch fan in operation; twenty minutes after the fan was stopped, concentrations in the workroom reached 280 p.p.m. Steps instituted to prevent a recurrence included more adequate exhaust ventilation, a carbon monoxide alarm and segregation of the furnaces from the main workroom.

The moral of this story would seem to be that a situation involving an extremely "close call" for a sizable group of workers might at any time be duplicated in many plants in Massachusetts and other states, and that operations such as the one in question call for more attention than they have been getting. — Reprinted from *Industrial Hygiene News Letter* (January, 1944).

MISCELLANY

NOTES

On February 28, Dr. Richard P. Strong, formerly professor of tropical medicine at Harvard Medical School and at present director of tropical medicine at the Army Medical School, Washington, D. C., was awarded a medal and an honorarium by the American Foundation for Tropical Medicine in recognition of his distinguished service in tropical medicine. The awards were made possible by a recent gift to the Foundation from the Winthrop Chemical Company, and will subsequently be given periodically for outstanding contributions in the field of tropical medicine, the medal to be known as the Richard Pearson Strong Medal.

The Trustees of Boston University have announced that Dr. Charles F. Branch, professor of pathology, has been appointed dean of Boston University School of Medicine. He will assume his new duties immediately, and succeeds Dr. Bennett F. Avery, who recently resigned to become director general of public health in Iran. Dr. Branch has held a teaching position in the medical school for the past eighteen years and has been professor of pathology since 1932.

CORRESPONDENCE

SIGNED VERSUS UNSIGNED BOOK REVIEWS

To the Editor: For many years I have had an interest in book reviews in medical journals. As a younger man not infrequently I wrote book reviews for the predecessor of the *Journal of the Boston Medical and Surgical Association*; in later years I have been at the other end of the book-review problem, reading reviews of my own publications. In each capacity I have thought that signed reviews were preferable to anonymous ones.

A book review can be a real contribution to medical literature in its style and content; not infrequently this actually happens with reviews in the field of general literature. But natural that, if one carefully reads a book and then fairly and comprehensively discusses its contents, he will like to credit for his work by his identity's being known. To read that the medical reading world is going to see who wrote the review seems to me calculated to stimulate a reviewer to make a greater effort to produce something that will be a credit to the writer and to check any tendency to careless reviewing. It is my belief that a plan of having signed reviews will bring to the work more capable reviewers. As a reviewer I should have preferred to have my name appear.

As an author my experience has been that reviews are very helpful toward better subsequent editions, and that this is one of the important usefulnesses of a book review, the other being to indicate to the reading public the content of the book and its quality as a guide to the desirability of its purchase. With reviewers, including critical ones, I have often had both delightful and extremely helpful correspondence. So I like to know to whom to write. Journals that publish unsigned editorials often say they will forward your letter to the reviewer and so allow you to have the advantage that might come from correspondence with the reviewer. I have tried this; either my letter remained unanswered, or the answer from the anonymous reviewer somehow did not seem to be the satisfactory results that came from correspondence with

a known reviewer, with whom you talked by letter as man to man.

Usually it is said that the anonymous reviewer is freer to criticize. That may be true, but it has not been my experience, for, by and large, signed reviews of my books have been just as critical as the anonymous ones, possibly even more so. My reviewers have not appeared to be afraid to be critical, and their criticisms have helped me, particularly when, by correspondence, I obtained elaboration of the criticism toward a better understanding of it on my part and in addition, what has been very helpful, numerous criticisms that had not been included in the published review. For the author I think signed reviews are a greater help than the unsigned.

I take it that the chief object of a book review is to be a help in the selection of books to purchase. Certainly, if the reader is aware of whose opinion he has seen, that opinion will carry increasing weight in proportion to the position in the medical world held by the writer of the review. It is my belief that in general a higher-grade medical man can be obtained to write signed reviews and that this type of man is entirely willing to say what he thinks of a book and less apt to be fulsomely uncritical of a book deserving condemnation rather than praise.

It seems to me that the policy long practiced by the *Journal* is not conducive to obtaining reviews of so high a grade of excellence or so helpful to readers and authors as would come from having signed reviews. Anyhow, why not try the other way for a while to see whether or not it is a better way rather than, without trial of the other way, persist in the present practice? If it does not seem preferable after a few months of trial, then return can be made to anonymity.

HENRY A. CHRISTIAN, M.D.

20 Chapel Street
Brookline, Massachusetts

MIDDLESEX UNIVERSITY SCHOOL OF MEDICINE

To the Editor: I am sure your readers are glad that the secretary of the Society has made public in your columns "the exact policy adopted by the Council on Medical Education and Hospitals of the . . . with regard to students from . . . being accepted by approved h . . ."

They may perhaps be interested in a statement which makes clearer than anything I have seen published some of the conditions under which this policy was formulated.

In June, 1942, I requested permission of the Council on Medical Education and Hospitals to make representation in person to it, concerning the question of penalizing action by the Council, in the case of a hospital approved by it if such hospital accepted as clinical clerks students from a school not approved by the Council. I had been told by a number of hospitals that they could not accept Middlesex students because the American Medical Association would not approve, but I had found by the spring of 1942 no authoritative written or printed statement supporting the contention of the hospitals.

Permission was granted to me and at the meeting in Atlantic City I told the Council briefly what I had been doing in Massachusetts about substandard medical education and especially what I had undertaken to do at Middlesex, and I asked the question to which I have referred, namely, "Will the Council withdraw approval of a hospital approved by it for the training of interns if such hospital accepts as clinical clerks the students from a school not approved by the Council?"

The letter from the Council, dated June 7, 1942, did not answer my question but contains the following sentence, "The Council did not feel justified in offering any approval or even encouragement in connection with your efforts, but we will await with interest any further report."

I laid the matter before the president (or maybe it was the president-elect) of the American Medical Association. He said in substance, "At least you are entitled to an answer to your question." So I wrote again, referring to what I called a "misunderstanding." The reply, dated June 19, 1942, reads in part as follows:

I am sorry if any misunderstanding has resulted from my letter of June 7. In connection with the approval of hospitals for internships, the hospitals deal individually

with the Council on Medical Education and Hospitals. As you fully realize, conditions vary greatly in the different hospitals and many of them are approved or removed from the list temporarily because of certain conditions existing at a specific time. The interest of the Council in this connection is solely the maintenance of a satisfactory educational program for the training of interns.

Hence if a hospital maintains such satisfactory standards the Council would not consider it within its field to decide whether or not it should accept students from any medical school as clinical clerks. . . .

Because of the possibilities of misunderstanding and because of the varying conditions existing in hospitals approved for internships, together with the responsibilities of the Council in the field of undergraduate medical education, the Council did not feel justified in making any general overall statement.

In spite of this disclaimer on the part of the Council, that answer sounds like a statement of policy. But it seems to have been in some respects not the right answer as is shown by the statement of the "exact policy of the Council" published in the January 20 issue of the *Journal*. I have been informed by the secretary of the Council that this policy was adopted on November 7, 1943.

It is the paragraph which I have quoted from the letter of June 7, 1942, which is most significant as indicating the background of the discussion. It is so important that I quote it again, "The Council did not feel justified in offering any approval or even encouragement in connection with your efforts."

What are my efforts? For eleven years as secretary of the Board of Registration in Medicine my efforts had been

School of Medicine to continue my efforts by attempting to improve that particular school.

It is not necessary to explain why I had not asked the approval or encouragement by the Council for my efforts except to point out that my own conscience was clear, to me a deciding factor.

If the justification for the existence of the Council is *their* effort to improve medical education, why their disclaimer as to "approval or even encouragement"? The principles on which my proposed action was to be based are highly orthodox, although I hope that some novel practices may be introduced in the course of time. Why, then, could no approval or even encouragement of *efforts* be offered?

But there the record stands. "The Council did not feel justified in . . . connection with your efforts . . . education. F . . . illuminating. . . one to think furiously."

BOOK REVIEWS

The Complete Pediatrician: Practical, diagnostic, therapeutic and preventive pediatrics. By Willburt C. Davison, D.Sc., M.D. Fourth edition. 8°, cloth, 256 pp. Durham, N. C.: Printed by Seeman Printery for Duke University Press, 1943. \$3.75 by check with order, or \$4.00 on credit.

This fourth edition differs little from previous editions, having been merely brought up to date so far as is possible with rapidly advancing medical information.

One's first impression on examining a book of this sort is one of bewilderment and helplessness. When, however, one has mastered the method of searching for information, the original emotion changes to one akin to awe that so much valuable, utilizable, up-to-date information is so readily available in such a small volume. In particular, there are many accurate and valuable tables, which not only include growth and diagnosis . . . each group . . . practicing physician.

In the reviewer's opinion the chief worth of this remarkable volume lies in its value as a book of reference to the student

and intern and to the general practitioner who may be confronted with pediatric problems.

Burns, Shock, Wound Healing and Vascular Injuries. Prepared under the auspices of the Committee on Surgery, Division of Medical Sciences, National Research Council. *Military Surgical Manual I.* 8°, cloth, 272 pp., with 20 illustrations. Philadelphia and London: W. B. Saunders Company, 1943. \$2.50.

The present war has brought into the armed services certain doctors who are ill equipped to deal with wounds and their many complications. The spread of specialization has made it impossible to recruit the large number of men who are needed and at the same time qualified to deal with war wounds. In the interest of efficiency, standardization of front-line and base-hospital practice is essential. The two-fold purpose of instructing the less experienced and of unifying practice among various units is well served by the military surgical manuals published by the National Research Council.

The volume on burns, shock, wound healing and vascular injuries is compiled by experts. It is thorough, concise and intensely practical. The keynote of the articles is proper treatment given early. Thus in severe burns the use of skin grafting is begun early; in shock, replacement therapy commences with the suspicion of shock; and in wounds, débridement is used within a few hours after injury.

Some of the problems discussed have not received their final solutions. The surface treatment of burns remains in a chaotic state. After outlining many measures of treatment the authors state:

It would be simple if one could be dogmatic and advise the use of one method, for example application of tannic acid, in treatment of all burns. However, it is now evident that it is unwise to try to apply any one method to burns of all degrees in all anatomic situations. Many other factors enter into the choice of local treatment. These include the availability of materials, time and space for certain of the methods, duration of time injury and so on. . . . Further experience may change the indications but possibly not the details of procedure of these methods.

The chapters on shock and fluid replacement are necessary for the war surgeon but contain much the same material as any recent volume on surgery. The chapter on skin grafting for contractures following burns is itself worth the price of the book. It is brief and yet has such a wealth of detail that one not widely experienced in plastic surgery can easily follow the procedures described. It will be of great interest to anyone doing general or plastic surgery.

Allergy. By Erich Urbach, M.D. With the collaboration of Philip M. Gottlieb, M.D. 4°, cloth, 1073 pp., with 395 illustrations and 59 tables. New York: Grune and Stratton, 1943. \$12.00.

This book covers the subject of allergy from almost every viewpoint and is really an encyclopedia on the subject rather than a textbook. The author presents in considerable detail the story of allergy from its genesis to the present and covers it in a most interesting and readable manner. The author in the preface states that he has attempted to give an impartial presentation of the conflicting views on controversial questions. He has succeeded admirably and presents his facts concisely and clearly.

The book is primarily one for the allergist, although certain chapters will have considerable interest for the general practitioner and specialists in other fields. Chapter 2, dealing with the basic principles of allergy, clarifies many of the difficulties of those unacquainted with the theories of this condition. This chapter and Chapter 19, devoted to the allergic diseases of the upper respiratory tract, should be valuable reading for most practitioners of medicine. One of the most interesting chapters is Chapter 23, which deals with allergic skin diseases, conditions that surely confront every physician, whether he is a general practitioner or specialist, sometime during his career. The facts in this chapter are presented with clearness, and the illustrations add considerably to the value of the text. In itself it constitutes a textbook that may well be read with profit by anyone seeking knowledge on the complex problems of allergic skin diseases.

Taken as a whole, although a bit unwieldy in size and voluminous in text, the book is a valuable contribution to the study of allergy and to the practice of this specialty. It certainly will be a desirable addition to the library of every practicing allergist and will earn a place for itself as a reference book in the library of the general practitioner.

Body Poise. By Walter Truslow, M.D. 8°, cloth, 312 p with 96 illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$4.50.

The writer has produced a useful treatise on physical education. The anatomy and kinesiology involved in maintaining good poise of the body is described in detail. There are helpful chapters on static disabilities of the feet, on the recording of a treatment of faulty posture and on lateral curvature of the spine. Various sports are analyzed in relation to posture. This book concludes with a glossary of anatomical terms and those unfamiliar with the nomenclature. This book should be of value to the physical educator and to the physiotherapist.

A Manual of Clinical Therapeutics: A guide for students and practitioners. By Windsor C. Cutting, M.D. 12°, cloth, 609 pp. Philadelphia and London: W. B. Saunders Company, 1943. \$4.00.

This is a compact, complete manual on treatment easily applicable to the care of disease in its wide range. It is well set up, and is based on the clinical and teaching experience of the author at Stanford, London and Johns Hopkins. It can be highly recommended as a textbook on clinical therapeutics.

Essentials of Syphilology. By Rudolph H. Kampmeier, M.D. With chapters by Alvin E. Keller, M.D., and J. Cyril Peterson, M.D. 8°, cloth, 518 pp., with 87 illustrations and 15 tables. Philadelphia: J. B. Lippincott Company, 1943. \$4.00.

This text presents all that its author claims. It is an excellent presentation of the concept of syphilis as a systemic disease. It stresses the value of complete history-taking, thorough physical examination, and emphasizes what syphilologists have learned by experience — namely, that clinical diagnosis must be supported by darkfield or serologic evidence of syphilis.

The reviewer believes that careful study of the clinical manifestations in the early stages of syphilis needs more consideration than the author stresses, because the future of the patient depends on the ability to recognize these lesions so that they will not be mistaken for those of late syphilis. The reviewer also believes that a diagnosis of syphilis can be made on two positive serologic tests alone. Furthermore, older syphilologists will not agree with the author's opinion in certain controversial questions — for example, the treatment of patients with a history of twenty years' duration who have no clinical signs.

There are other minor points to which the syphilologist might take exception; the book is written, however, for the student and the general practitioner, and the reviewer recommends it as a practical, comprehensive guide for diagnosis and proper treatment. The discussions of the medical aspects, prevention and control of syphilis are carefully presented, and the suggested methods of therapy are authoritative. The book is easily read, well printed and abundantly illustrated, and will make a useful addition to the library of the student, general practitioner or specialist.

Whooping Cough. By Joseph H. Lapin, M.D. 8°, cloth, pp., with 25 tables. Springfield, Illinois: Charles C Thomas, 1943. \$4.50.

The author brings into this book his own wide experience in the prevention and care of whooping cough, as well as an extensive review of the literature. The chapters on bacteriology, pathology and immunity reflect his intimate knowledge of the subject. The chapters on the prophylaxis of exposed children and of contacts are sound expositions of a highly debatable matter. Here, as in the chapter on treatment, he keeps his feet well on the ground and points out what is based on pure speculation and what is of proved value. Furthermore, he gives facts and figures to show the real value of different methods of dealing with this extremely variable disease. The only criticism one can make is that the author seems to have hurried over the chapters on complications and on public health recommendations. It is hoped that in subsequent editions these chapters will be brought up to the high level of the rest of the work. The book should be invaluable to every pediatrician and to all practitioners who are confronted with the problem of whooping cough.

Number 10

THE PSYCHONEUROSES OF WAR*

COMMANDER J. L. HENDERSON (MC), U.S.N.R., AND MAJOR MERRILL MOORE, M.C., A.U.S.†

PASADENA, CALIFORNIA, AND BOSTON, MASSACHUSETTS

WE are here reporting findings obtained from a study of the first 200 neuropsychiatric cases admitted to a hospital of the United States armed forces somewhere in the South Pacific. This paper presents a statistical survey of the main findings, with a brief interpretation.

The importance of the problem of psychoneurosis in war is reflected in the fact that the number of neuropsychiatric cases rose from 12 to 17 per cent of total admissions during the first four months the hospital was in operation. Furthermore, an additional 6 per cent of cases were transferred to the Neuropsychiatric Service within the hospital as the result of consultations that revealed concurrent neuropsychiatric disorders. Thus, the neuropsychiatric cases among the total admissions amounted to 23 per cent, or approximately 1 case out of 5.

The distribution of these neuropsychiatric cases according to diagnosis is as follows: anxiety neurosis, 49 per cent; hysteria, 20 per cent; constitutional psychopathic state, 7 per cent; schizophrenia, 6 per cent; manic-depressive psychosis, 5 per cent; epilepsy, 4 per cent; and miscellaneous disorders, 9 per cent.

The term "war neurosis" is not used here since we have come to believe that a clearer picture of the neurotic reaction is obtained from the standard classification. In most of these cases it appeared that the hysterical mechanism was essentially a means of immobilizing anxiety by converting it into a symptom that resulted in relative freedom from anxiety at the expense of loss of physical or mental function. This process was seldom complete, so that an admixture of anxiety and hysteria was often found in the same patient. In arriving at a diagnosis hysterical reactions were emphasized because they appeared to be of more serious import than others and affected the prognosis accordingly. It is interesting to note that the percentage of cases

with anxiety neurosis was originally higher and continued so until recently, when a group of 70 patients arrived. Half of these were Army patients and over half of them were found to have hysteria, many of them giving a history of severe amnesia, which in some cases persisted on admission.

In attempting to analyze predisposing conditions, the most important factor was found to be a disturbance in the family background. This was strikingly constant in almost every case. Those patients who came from homes that were broken by separation, divorce or death, or distorted by neurotic parents, were found to have personalities insufficiently developed to deal rapidly or adequately with the problems of life, particularly with the problems of war. On the basis of the histories given by the patients — which in most cases have been accepted as reasonably reliable — we have attempted roughly to estimate this disturbance in the home environment as follows: normal, 4 per cent; slightly disturbed, 25 per cent; moderately disturbed, 42 per cent; and severely disturbed, 29 per cent.

These patients were all young men; 70 per cent were between the ages of seventeen and twenty-five. Six per cent had entered college. One third of the entire group had completed high school. Fifteen per cent had completed the eighth grade only, whereas 8 per cent had not gone that far. Their educational accomplishments were not considered remarkable or directly related to the type of psychoneurotic reactions that later developed.

One striking feature was that 30 per cent of the entire group gave a positive history of head injury associated with unconsciousness lasting fifteen minutes or longer, prior to entering the service. In most cases, however, this episode bore no obvious etiologic relation to the later developed psychoneurosis. But it is assumed that this previous head injury, in certain cases, may have been a contributing factor, by lowering the patient's resistance or adaptive capacity, or possibly by making him more susceptible to fatigue and impairing his repressive powers.

*This article has been released for publication by the Division of Publications of the Bureau of Medicine and Surgery of the United States Navy. The opinions or assertions contained herein are the private ones of the writers and are not to be construed as official or reflecting the views of the Navy Department or the Naval Service at large.

†Associate in psychiatry, Harvard Medical School, assistant visiting psychiatrist, Boston City Hospital (on leave of absence).

Thirty-five per cent of the patients had previously experienced a psychic trauma of a sudden and overwhelming nature comparable to that of the combat situation. The commonest form of this traumatic experience was an automobile accident. The usual reaction was that of being shaky or jittery for a short time and being afraid of riding in an automobile or driving one for a longer time. Of those who had seen combat, 85 per cent had been suddenly upset by exploding bombs or heavy shelling near them. Some had been rendered unconscious and some had become acutely hysterical. It was difficult to determine the reactions accurately from the records available and from the patients' accounts, but the following is a fairly accurate résumé of what happened: unconscious, 50 per cent; dazed, 22 per cent; "went to pieces," 10 per cent; "bounced" (not unconscious), 8 per cent; amnesia for the event, 5 per cent; blindness (hysterical), 3 per cent; and "frozen," 2 per cent. Many of those rendered unconscious or dazed also had amnesia after recovering consciousness. Likewise, many of them became hysterical or "went to pieces" on regaining consciousness. Usually these reactions recurred during subsequent air raids and shellings.

The factors of fatigue and of intensity and frequency of repetition of traumatic stimuli are indicated by the number of weeks the patients were able to carry on in the combat zone before the development of a manifest psychoneurosis. Thirty-five per cent broke down in the second and third weeks, 10 per cent in the fourth week, and 35 per cent in the tenth, eleventh and twelfth weeks. No psychoneurosis occurred in the sixteenth to nineteenth weeks, and only 1 patient became ill in the twentieth week. Eight per cent of the acute disturbances occurred as the result of action at sea. These figures are correlated in part with the strain of combat action, in part with fatigue, and in part with constitutional inability to withstand and recover from traumatic stimuli. It is our impression that of these factors the constitutional predisposition or the neurotic makeup of the patient is the most important

organic brain damage that complicated the psychoneurotic reaction and unfavorably influenced the prognosis. This occurred in 12 per cent of those who had been subjected to bomb or shell blast. Another complicating factor was a schizoid personality without psychosis. This occurred in 10 per cent of the cases evacuated from the battle area. In about half these the diagnosis of prepsychotic personality would have been more accurate.

It was noted that many of the patients when on liberty, particularly their first one after return from combat, imbibed alcohol too freely. When questioned about this, their reply was that they used it "to forget." This correlated with the anxiety symptoms and with the psychic distress associated with them. The patients with hysteria, being relatively comfortable, drank less. Those with anxiety symptoms for the most part did not persist in their drinking because they quickly learned that the relief they obtained did not last very long. Alcoholism *per se* occasionally occurred as a symptom but was in no way a definite or a major problem, although alcoholic beverages were available. On the whole, the part alcohol seemed to play in the picture was a beneficial one. It was generally used as a relaxing agent for purposes of recreation, — usually in a social setting, — and to relieve or ameliorate the tension and the frustrations of war. Occasional moderate drinking when off duty or on leave is a part of the pattern of military life.

Loss of weight in the battle area was tabulated as an indication of the effect of the stress of battle conditions, and was also considered to be a fair measure of the physical-fatigue factor. The weight loss averaged twenty-two pounds over a period of one to twenty weeks. There is considerable approximation in this figure, but it is reasonably accurate (as one of our patients remarked, "There were no scales on the island"). In the early weeks after occupation, the rations of many of the combatants were considerably substandard — rice and cocoanuts, and of these only enough for one or two meals a day.

bat zone. This finding correlated over 95 per cent with anxiety symptoms. Enuresis in childhood had occurred in 15 per cent, but few had developed this symptom as the result of combat. There was no special relation of bedwetting to the particular psychoneurosis that the patient later developed. Walking and talking during sleep had occurred in 20 per cent of the cases and persisted in a few up to the time of admission. This was limited to those who developed hysteria.

Nightmares occurred almost universally among these patients, even after they had been evacuated to a place of safety, and they were severe enough to wake them. The patients reported that in their dreams they were terrified and often felt paralyzed — "I couldn't move" — "I couldn't run" — "I couldn't shoot my gun." Their psychic disturbance was so severe that the usual protective dream mechanisms failed to operate. The anxiety broke through, and not only woke the patient but also flowed over into the sympathetic nervous system and produced sweating and shaking comparable to the nocturnal terror reactions occasionally observed in disturbed children. Some patients vomited after their nightmares and attacks of nocturnal terror. Repetitive dreams of combat were absent only in the psychotic patients and in a few of the markedly hysterical patients who could not remember what they had dreamed. There was a tendency among the patients to talk about their dreams and relate them to each other, apparently on a cathartic — and slightly competitive — basis. At any rate, they appeared to get some relief from this sharing of anxiety. It appeared to be a sort of group autotherapy, which in most cases was more effective than were the attempts made by a few patients to repress their anxiety altogether. Most of the patients showed a tendency to talk about their combat experiences, which at times approached a compulsion. This was encouraged as a form of group therapy.

The recounting of dreams and the reiteration of combat experiences were interpreted as an attempt on the part of the patient — pushed by an inner drive, or unseen necessity — to relive and master or to be successful in a situation that had previously mastered him. It was as if the patient was utilizing the dream and the retelling of his experience in a new and relatively safe situation to desensitize himself from a strongly emotional conditioning that had originally and recently occurred in the face of actual danger. Since there were few opportunities for intensive individual psychotherapy, all group efforts of this type were encouraged and were utilized to the utmost. These efforts, however, were seldom entirely successful in the short time the patients were able to remain in the hospital, but they were not without certain benefits. In some cases, just as the dreams woke the patients, so did certain patients have to leave the group of patients who were

retelling their combat experiences or leave motion pictures that showed bombing and shelling. In such cases it was obvious that the anxiety accumulated faster than the patient could cope with it. An example of this occurred when "Mrs. Miniver" was shown near the hospital. Most of the neuropsychiatric patients had to leave when the "blitz" in the picture began, and most of them required extra sedation that night. On the whole they seemed better able to adjust themselves to noisy radio programs or excited newscasts received acoustically than they did to the visual stimulation by motion pictures. A possible reason for this was the fact that they had the power to turn the radio off if it became too disturbing, whereas with a motion picture they had to leave, thus absenting themselves bodily and again excluding themselves from the group that was remaining and even enjoying it. Many interesting and subtle individual and group reactions along these lines were observed.

As compared to bombs and shells, rifle and machine-gun fire seldom precipitated a neurosis. One reason for this was summed up in a statement so often made by the patients, "You can't fight a bomb." Many of the patients seemed to recognize that activity, action and motion in a tense and dangerous situation are of great therapeutic and stabilizing value in draining off the excitation as rapidly as it is produced. Many of them were in situations where they could not do this. Most of them were forced to lie in foxholes or hidden in brush or crouched behind trees for hours and had to take extremely heavy bombing or artillery fire. At night they had to remain motionless for hours close to the enemy, often under mortar fire.

It must be remembered that here we saw only those who were able to control their impulse to run or those who were held and prevented from doing so by others, as was often the case. Several of the patients told of seeing others who ran from covered positions, only to be blown to bits. Often they added, "I'm afraid I might do that if I went back." From these and similar observations and from the details of breakdowns reported by these patients it is apparent that if action or adequate emotional release does not occur, the pressure of the accumulated excitation breaks through the personality, fracturing it, — by short-circuiting the cortex, — and discharges into the nervous and muscular systems, resulting in primitive instinctual patterns of behavior. Such actions are inappropriate and may be fatal. This excitation also discharges into the autonomic nervous system, as indicated by rapid heart action, rapid breathing, sweating, frequent urination and occasional vomiting, which were interpreted as abnormal only when they recurred outside the traumatic situation. There was also frequent defecation, but the prevalence of dysentery made this hard to evaluate as a symptom. This disruption of the personality was recognized by the

patients, as indicated in their spontaneous statements: "I'm not the same any more" — "Nothing interests me since I was bomb-busted" — "Things aren't the same." They were unsure, shaken, emotionally defeated and ready momentarily to retreat. They had lost self-mastery and self-confidence and had found themselves at the mercy of hostile and overwhelming forces — both external and internal. They may be again overwhelmed. It is this situation that creates anxiety, which *per se* calls up further excitation. Thus the vicious cycle of this psychoneurosis becomes established. Any sudden sound will call up additional excitation, which, if strong enough, will push through the personality in the places already ruptured and result in primitive protective movements or in the diffuse expressions of fear and impotence, such as crying, shaking or heedless muscular movements, that are so commonly observed.

Previous mention has been made of the frequency with which these patients came from broken or distorted homes, and we re-emphasize the opinion that this is the most important of all the predisposing factors that have been analyzed.

In studying the home background a certain pattern became apparent. The mother was found to stand out. She was usually a "nervous" woman and had often had a nervous breakdown but was rarely hospitalized for it. She was easily excitable and quickly "went to pieces" under stress. She tended to worry, particularly about her children, and to be overly concerned about them. For example, most of the mothers had waited up for their boys to come in at night up to the time that they entered the service. The father seemed to be in the background. He was away at work much of the time, and when he was at home it appeared that he was not much interested in or affectionate toward the children. About half the fathers drank to excess. From these observations the following interpretation is made: The mother is an immature person who feels herself insecure and in her marriage tends to establish a childish dependent relation to her husband. This, somehow, is not successful; the reason is not clear. It may be that the husband is also trying to establish a similar relation, as indicated by the frequency of alcoholism. The mother accordingly makes many compromises but remains insecure and identifies herself strongly with her children. Along with her insecurity she also vaguely senses that the world is hostile. Her subconscious thinking may then run along these lines: "If the world is bigger than I am, it may overwhelm me; it is hostile. I shall therefore feel hostile toward it"; or, "If the world is hostile, then I can make no attachment to it, therefore I shall make a doubly strong attachment to my children." So it may be that she and her children come to form a unit and feel together, relatively helpless in a hostile world. They are unable to do anything about this except to suffer and to repress their

natural counterhostility. The chief result of this is that the mother and the child never learn to deal with hostility, particularly the child, who later becomes a patient.

As previously mentioned, the father was in the background most of the time. When he was drinking, however, there frequently occurred an explosion of verbal and often physical abuse, to which the mother usually reacted by an attitude of hopelessness and defeat, with fearfulness and anxiety in the intervals. In this way the acceptance of the overwhelming nature of hostility may have become established in the patient along with the necessity to avoid it.

In studying the relations between the patient and his mother, these points come out again and again, and are corroborated by the letters the mother sometimes writes to her son who is in combat. Often her letters are anxiety laden and disturb him accordingly. Without denying the possibility that this is a natural reaction on the part of any mother whose son has gone forth to battle and may be killed, it is a fact, vouchsafed by many, that when he went into combat he was more worried about the situation at home — as it had been relayed to him by his mother — than he was about himself. One patient stated flatly:

I wasn't worrying about myself so much as I was worrying about my mother and how she would feel if anything happened to me. I knew that she would be worrying if she knew, or she would be worrying anyway, so I guess I worried. She always worried a lot about me and about everything else. She was the worrying kind and that made me that way. She had a nervous breakdown when I left home and wrote and told me all about it. She made me feel that it was my fault. That was what was on my mind when we attacked, so I couldn't do much good.

This is a typical verbatim statement. It was repeated many times by soldiers, sailors and marines.

This vicious emotional cycle in the family setup was repeatedly described, and in nearly every case a mutually dependent neurotic relation existed between mother and child. The mother, in view of this emotional need, unconsciously tended to perpetuate this relation and thus attempted to prevent the son's growing up, since in so doing he would outgrow his need for her. Such a loss seems to be as great as though she had lost a part of herself. It is this child-to-child relation that she understands best and that holds the least danger from her point of view. The child's growing up and breaking away thus becomes a hostile act. But the mother cannot express her counterhostility, for this would more surely lead to the loss of what she is trying to hold. This situation leaves little room for either hostility or love, the latter of which on the mother's part would move her in the direction of aiding the child to develop into an independent adult. This inhibited emotional energy seems to find a common outlet in worry and concern. In the light of this situation the child remains immature, insecure and dependent and re-

flects the mother's shortcomings. He does not acquire security within himself. He can attain adulthood only by breaking his mother's hold (rebellion). Attempts in this direction produce such pain and suffering on the mother's part and lead to situations where he feels such insecurity and anxiety that he comes into the service with the fundamentals of this interdependent relation still essentially unchanged, not having dealt with his stronger forces — having lived a life chiefly receptive and more identified with his mother than with his father. Thus, it would appear that in the combat situation, being oriented toward life in a receptive way, he is more concerned with what is coming at him from the enemy than with what he is sending toward the enemy. The conscious complaints and the dreams of these patients were universally passive and receptive — "bombs falling on me" — "being chased by a shell" — ". . . shooting at me" — ". . . running at me with knives." Rarely was the patient shooting at the enemy, and then the story was usually, "I pulled the trigger but my gun wouldn't go off" or, "I tried to attack them but my arms wouldn't move" and so forth. In this respect it may be mentioned that a great many patients spoke of interesting relations between killing and sexual excitement that they experienced. There were also many psychosomatic relations, particularly those shown by asthma, peptic ulcer and rapid heart action, that were especially interesting because of their onset under combat conditions. In general it can be said that these patients, never having dealt adequately with their outgoing forces, — for example, hostility and aggression, — find themselves overwhelmed in a situation of combat that calls up these emotions in such extreme degrees.

It seems that the man who has developed a so-called "war neurosis" was predetermined before he entered the Service. It might even be said that war neuroses are "made in America" and only come to light or are labeled in combat. It is certainly a striking and a most significant fact that the majority of normal soldiers, sailors and marines do not break in combat although they are exposed as long and as fiercely as are those who do. Those who carry on the longest before they break have the best prognosis. The men who arrive at the zone of combat with an attitude of defeat are the ones who break down the quickest, some of them on the first day or after the first few shells or bombs. These are the ones who have the poorest prognosis and do not want to get well. They are "through." The war is over so far as they are concerned, and all they want is to go home. Thus their symptoms acquire a tremendous secondary importance. They are the ones who are always full of complaints, utilize and magnify their symptoms, and are perfectly hopeless so far as any use in the war effort is concerned. The attitude of the patient is more important than his symptoms, and it determines whether or not he

wants to get well and whether or not he wants to fight.

The killing of a "buddy" is of great importance. It appears that every serviceman goes into war with the philosophy, "It can't happen to me." This belief is severely shaken when a man with whom he has so strongly identified himself is killed. In a sense it is "me" being killed, and so the death is intolerable. Many of the men were extremely upset when this happened and were not upset until it did. In many cases it appeared to be the precipitating factor of the illness.

Our time has been almost entirely occupied with examinations, the recording of histories and findings, the making of diagnoses and dispositions, consultations, and the supervision of patients. Therapy has accordingly been limited. The foremost problem was that of anxiety and uncertainty, with restlessness, jumpiness and insomnia. Deeper lying were the attitudes of bewilderment and defeat and hysterical conversion symptoms. The quickest approach to the surface symptoms was through sedation, principally with phenobarbital. On one ward this was made optional and restricted to the night. All the patients were told on admission that sedatives had been ordered for them but would be given only on their request when they were unable to sleep. This was done to avoid the feeling of being dependent on sedatives, — loss of mastery with a wish to be and fear of being overwhelmed, so often the basic conflict in anxiety states, — which itself may give rise to further anxiety and defeat the action of the sedative. The patients were told to use sedation as a man with a sprained ankle would use a cane. On another ward all the patients received sedation, disguised as a tonic, three times a day. The patients did not remain in the hospital long enough for a definite evaluation of these two methods, but the ward where the sedation was given regularly was the quieter of the two. Hydrotherapy was not available. Occupational therapy was instituted as the last third of this group of patients was passing through the hospital. In single cases it was of great value, and it has since grown to fill an important place. Hypnotism was used in a number of cases by one of us (M. M.). This resulted in obtaining the pattern of the underlying conflict in a quick, clear way. It was also useful in clearing up amnesias, anesthetics, paralyzes and other hysterical symptoms. In general it was found to be a useful adjunct to therapy of the underlying pathologic emotional patterns.

So far as time permitted, group therapy was employed. This was restricted to one ward, containing about 30 patients. A brief explanation of the nature of their illness was given them in the first interview, with stress on the similarity of their symptoms. In subsequent interviews the patients asked questions that were usually requests for an explanation of their symptoms. At times they tended toward testi-

monial meetings, at first with surprise that others had had experiences so similar. Group feeling was rapidly built up, with a tendency to pattern behavior after the patient who made the most rapid progress. The explanation given was superficial, with emphasis on encouragement. The patients did not remain in the hospital long enough for us to go into the deeper aspects of their illness or to evaluate the efficacy of the therapy.

Because these psychoneuroses had their origin in distortions of personality development, we believe that the only lasting therapy is of the individual type in which an alteration of the personality structure is effected. The first step consists in creating a feeling of confidence between physician and patient, which when it becomes stronger than the fear can be used to help the patient deal with his stronger feelings — in divided doses. Because of his confidence in the physician, anxiety is lessened and the vicious cycle previously referred to is broken or avoided. With a growing feeling of accomplishment in doing this — occupational therapy has similar action — the patient is able to deal with ever-increasing amounts of excitation and thus slowly rebuild his personality — mend the fracture. From one point of view this is a retesting of life situations, with guidance in the direction of mastery that should have been accomplished in childhood by the parents. Early treatment is important before elements of secondary gain — attention, sympathy,

display of symptoms, compensation and so forth — give value to symptoms and create a barrier to treatment. Individual treatment is of course impossible in the war situation because of the large number of cases and the few psychiatrists in proportion to the time required.

For practical purposes the person who has once broken under the stress of battle is no longer able to do combat duty. We believe, however, that much could be done in the matter of rehabilitation, the avoidance of the sense of defeat and failure, and furtherance of the war effort if selected patients could be, as a group, assigned to noncombat duties in keeping with their abilities and maintained under psychiatric supervision with such therapy as could be given.

SUMMARY

The findings from a study of 200 neuropsychiatric cases that occurred under combat conditions are presented, and a statistical analysis is reported.

The usual psychoneurosis, with the underlying faults of the personality, is outlined. The origin of this difficulty appeared to be in the immature interpersonal relation that existed between the parents and the child when the latter's personality was in the formative period.

The limited therapy employed is indicated, and suggestions with regard to further treatment are offered.

MENINGITIS IN CHILDREN*

A REPORT OF TWENTY-EIGHT CASES

CHARLES H. HOLLIS, M.D.,† AND JAMES MARVIN BATY, M.D.‡

BOSTON

MENINGEAL infection in children is fairly common, and in recent months there has been an increasingly high incidence of the disease,¹ particularly of meningococcal meningitis, in some places approaching the proportions of an epidemic. Twenty-eight consecutive cases of meningitis treated at the Boston Floating Hospital between June, 1941, and June, 1943, are included in this report. This period is chosen because it includes all the cases of influenzal meningitis in which type-specific anti-influenza rabbit serum was used.

It will be seen from Table 1 that the cases in this series fall mainly into three etiologic groups, — namely, 9 cases of influenzal meningitis, 12 of meningococcal meningitis, and 5 of pneumococcal meningitis, — with 2 miscellaneous cases, due respec-

tively to the colon bacillus and to a *Salmonella*. The relative incidence is at variance with figures that show the commonest type of meningitis in children to be tuberculous,^{2,3} and it is at least encouraging to see less of this form of the disease. The cases cover a relatively limited age group: all but 3 of the patients were below the age of three and a half years, and this is in keeping with the lack of preponderance of the meningococcal form. Colon bacillus meningitis is not rare in early infancy,³⁻⁵ although it is at every other age.⁶ Cases of *Salmonella* meningitis are apparently unusual.⁷

Influenzal Meningitis

In the group of 9 cases of influenzal meningitis, the age incidence varied from four months to three and a half years, and in all cases but 1 the patient was admitted to the hospital within five days after the onset of the disease. These two factors — the age of the patient and the duration of the infection

TABLE 1. Analysis of 38 Cases of Meningitis.

CASE No.	NAME	SEX	AGE	DURATION BEFORE ADMISSION	TOTAL DURATION*	OUTCOME	ORGANISM	DRUG	SULFONAMIDE MAXIMUM BLOOD LEVEL, mg. %	SERUM	REMARKS
5064	E. K.	F	1 1/2 yr.	20	50	Died	<i>H. influenzae</i> (Type B)	Sulfathiazole	15.0	6 amp.	Evidence of block
5067	S. B.	M	1 1/2 yr.	2	40	Recovered	<i>H. influenzae</i> (Type B)	Sulfathiazole	1.8	7 amp.	
5107	S. N.	F	1 1/2 yr.	4	24	Recovered	<i>H. influenzae</i> (Type B)	Sulfadiazine	6.0	1 amp.	
5510	D. B.	M	2 10/12 yr.	3	21	Recovered	<i>H. influenzae</i> (Type B)	Sulfadiazine (I.V.)	24.0	5 amp.	
5511	M. B.	F	9/12 yr.	2	7	Recovered	<i>H. influenzae</i> (Type B)	Sulfadiazine (I.V.)	10.5	3 amp.	
5635	M. G.	F	3 6/12 yr.	2	13	Recovered	<i>H. influenzae</i> (Type B)	Sulfadiazine (I.V.)	16.0	4 amp.	
5582	P. H.	M	9/12 yr.	5	15	Recovered	<i>H. influenzae</i> (Type B)	Sulfadiazine (I.V.)	10.6	7 amp.	Otitis media; blood culture positive. Diffuse bilateral bronchopneumonia
6060	N. W.	F	4/12 yr.	1	3	Died	<i>H. influenzae</i> (Type B)	Sulfadiazine (I.V.)	22.8	3 amp.	
6117	S. F.	F	1 10/12 yr.	2	21	Recovered	<i>H. influenzae</i> (Type B)	Sulfathiazole (I.V.)	17.0	10 cc polyvalent	Meningococcemia; rash
5531	W. G.	M	1 11/12 yr.	1	6	Recovered	Meningococcus	Sulfathiazole (I.V.)			Eliminating meningococcemia, with rash. Waterhouse-Friderichsen syndrome; spinal-fluid culture positive.
5567	L. V.	M	2 yr.	3	12	Recovered	Meningococcus	Sulfadiazine			Waterhouse-Friderichsen syndrome; spinal-fluid culture negative.
5812	D. C.	F	7/12 yr.	10	20	Recovered	Meningococcus	Sulfadiazine			
6183	P. M.	M	2 1/2 yr.	3 1/2	3 1/2	Died	Meningococcus	Sulfadiazine			
6387	A. S.	F	9/12 yr.	3 1/2	3 1/2	Died	Meningococcus	Sulfadiazine			
6244	P. K.	F	3 yr.	10	16	Recovered	Meningococcus	Sulfapyridine (I.V.)	34.0		
6278	G. M.	M	1 9/12 yr.	5	8	Recovered	Meningococcus	Sulfadiazine	21.8		
6307	P. K.	F	2 3/12 yr.	3	7	Recovered	Meningococcus	Sulfadiazine	22.4		
6376	D. L.	M	5 yr.	1 1/2	2 1/2	Recovered	Meningococcus	Sulfadiazine	12.8		Rash; blood culture negative; spinal fluid on admission clear, with positive culture; spinal fluid next day cloudy with negative culture.
6464	J. F.	M	9 10/12 yr.	1	5	Recovered	Meningococcus	Sulfadiazine	15.0		Rash
6486	R. G.	M	10 yr.	4	11	Recovered	Meningococcus	Sulfadiazine	14.8		Evidence of block; pneumococci; spinal-fluid culture always positive.
6498	R. S.	M	8/12 yr.	2	8	Recovered	Meningococcus	Sulfadiazine	14.8		
5671	C. T.	M	6/12 yr.	3 1/2	18	Died	Type 7 pneumococcus	Sulfadiazine	18.0	40,000 units	
5948	M. H.	F	1 2/12 yr.	1	14	Recovered	Type 19 pneumococcus	Sulfadiazine (I.V.)	45.0	360,000 units	
6076	M. R.	M	2/12 yr.	3 1/2	12	Died	Type 23 pneumococcus	Sulfadiazine (I.V.)	52.0	140,000 units	Blood culture positive
6227	M. S.	F	8/12 yr.	2	3	Died	Type 4 pneumococcus	Sulfapyridine (I.V.)		40,000 units	Blood culture positive, patient died 17 hours after admission.
6293	C. B.	M	3/12 yr.	6	7	Died	Type 5 pneumococcus	Sulfadiazine and Sulfapyridine (I.V.)			
5136	A. M.	F	6 wk.	14	21	Recovered	Colon bacillus	Sulfathiazole	2.5		Blindness developed owing to optic atrophy.
5170	B. L.	M	5 wk.	14	56	Died	<i>S. oranienberg</i>	Sulfathiazole	8.2		Evidence of block; multiple walled-off abscesses.

* Duration to the first spinal-fluid culture that was sterile or to the day of death.

prior to treatment — seemed to have an important bearing on the outcome. Of the 2 patients who died, one (E. K.) had evidently had meningeal infection for at least twenty days prior to admission, and the ventricular block that occurred had probably developed previously. Because of large amounts of fibrin in the spinal fluid, block is a likely complication of this type of meningitis.⁸ The second patient who did not survive (N. W.) was a four-month-old infant, the youngest in the group. She had apparently had meningitis for only one day prior to admission, but she was highly toxic and moribund and had a diffuse bronchopneumonia.

In the management of these cases an attempt was made to follow a definite plan, such as has been suggested in several recent articles.⁹⁻¹² In all cases the organism was found in the direct smear of the spinal fluid soon after admission and was typed directly from the spinal fluid. The organism in each case was the Type B influenza bacillus; this is true in the majority of influenzal infections in children.^{10, 11} The bacteriologic diagnosis was confirmed by culture of the spinal fluid and the blood. The total and differential cell counts of the spinal fluid indicated the presence, but not the severity, of the meningeal infection, and afforded a convenient means of following the course. The spinal-fluid sugar was usually, but not always, reduced, and usually increased progressively as the infection subsided. The correlation between an extremely low spinal-fluid sugar and an extremely severe infection has been emphasized elsewhere.¹⁰ In these cases the results were too varied to confirm this, and it was thought that the sugar had mainly a qualitative value. The spinal-fluid protein was elevated in every case.

Treatment was directed toward two ends: the general supportive measures required by any acutely ill patient and the specific measures against the infection. Several of these patients were semicomatose and irrational and in moderately severe medical shock, owing to loss of fluids from refusal of feedings, vomiting and so forth, and it was impossible to administer fluids and medications orally. In 7 of the 9 cases, a continuous intravenous injection was started immediately, and everything was given by this route until the patient was able to take and retain things by mouth. Such an intravenous injection usually ran continuously for twenty-four to forty-eight hours, and when necessary a second vein was used. Thus fluids were started immediately and given in amounts that supplied the patient with between 1000 and 15,000 cc. every twenty-four hours, depending on his weight. In these cases it was possible satisfactorily to correct and control dehydration and acidosis with physiologic saline and glucose solutions. Satisfactory results were observed in several cases in which the solutions were alternated — that is, first normal saline solution and then 7.5 per cent glucose in water (which is slightly hypertonic, and can be given safely intravenously).

This was done to avoid the danger of overloading the patient with sodium chloride and producing edema. When shock was present, plasma and whole blood were used, the latter because of the anemia that may develop secondary to infection and to large doses of sulfonamides.

Further general treatment consisted largely of nursing care and symptomatic management of the manifestations of cerebral irritation and elevated intracranial pressure. Convulsions were controlled by sedation: a mixture of equal parts of sodium bromide and chloral hydrate, given as a retention enema, was found to be a helpful sedative, particularly in small infants. The symptoms of excessive intracranial pressure were relieved by lumbar puncture, letting the fluid flow slowly and removing only a small amount at a time. If there was evidence of blockage of the ventriculospinal system, — that is, if only a small amount of fluid was obtained and the symptoms were unrelieved, — cisternal or ventricular puncture or both were done. In most of these cases frequent lumbar punctures were avoided; one was done on admission to determine the diagnosis, and thereafter two or three taps were made to follow the course of the disease.

The specific treatment consisted of the use of sulfonamides in large doses, and of type-specific anti-influenza rabbit serum. The relative benefit of the two types of therapy could not be evaluated because all cases received both sulfonamides and serum.* In all but 2 cases the drug employed was sulfadiazine, because of its relative freedom from toxic side effects,^{14, 15} and because of its purported ability to filter readily through the choroid plexus and produce a relatively high level in the spinal fluid.¹⁴ The drug was used intravenously in all the cases that were admitted after the soluble form of the drug (the sodium salt) became available, and the administration of the drug offered no difficulties; it was simply added at appropriate intervals to the continuous intravenous injection already running. Specifically the dosage for the first few days of illness in these children was between 2 and 4 gr. (0.13 to 0.27 gm.) per pound of body weight, averaging 3 to 3½ gr. (0.20 to 0.23 gm.), given intravenously in a 5 per cent solution. The dose was increased or decreased according to the level in the blood, an effort being made to maintain this level at 10 to 15 mg. per 100 cc. Only 2 of the 9 patients in this group reached levels of over 16 mg., and their recoveries were no more rapid or spectacular than those of any others. As soon as possible the dosage was diminished in every case, and as soon as the patient could retain fluid and drug by mouth the intravenous

*One patient (S. B.) showed a maximum blood sulfadiazole level of 1.8 mg. per 100 cc., lower than that of any other patient, and usually regarded as insufficient to effect therapeutic action of the drug. The fact that he survived speaks for the importance of the serum, of which he received large doses over a long period. On the other hand, encouraging results have been reported with chemotherapy (sulfadiazine) alone.¹⁵

†In a few cases, simultaneous levels were taken in the blood and spinal fluid, and the spinal-fluid levels were found to be between two thirds and three quarters of the blood levels. These findings seem to agree with those of others.^{11, 16}

route was discontinued, usually in thirty-six to forty-eight hours. No serious untoward results from the drug were observed, but experience in this group of cases was limited almost entirely to sulfadiazine. One case has been reported of fatal nephritis from sulfathiazole that developed during the treatment of influenzal meningitis with this drug in combination with sulfapyridine.¹⁷ Reports indicate that results obtained with sulfapyridine have in general been better than those with sulfanilamide.^{18, 19} Whether the height of the blood level of the drug over a certain point has any bearing on the outcome of the treatment is difficult to decide.^{11, 20}

The specific antiserum was given as soon as the bacteriologic diagnosis had been made. Two types of serum are available: horse serum^{8, 21} and rabbit serum.^{22*} All these patients were given rabbit serum, which was injected intravenously and allowed to run into the vein slowly, dissolved in several times its volume of normal saline solution, so that each ampoule (25 mg. of antibody nitrogen) took at least two or three hours to run in. All patients were first skin tested, but no positive reactions were found. From one to three ampoules (25 to 75 mg.) were given the first day, and thereafter the dosage was determined by the actual titer of antibody in the blood, as measured by daily Quellung tests. In the recent cases, the Quellung test was done with the patient's serum in a dilution of 1:10, to ensure the presence of antibody in more than necessary abundance, according to a published suggestion.¹⁰ It has also been recommended that the patient be kept desensitized by giving small doses of antiserum fairly frequently until recovery is assured.²¹ The patients in this group received 4 to 5 ampoules. Two patients who survived were given only 1 and 3 ampoules respectively, and 2 received 7 ampoules each. We have had no experience with this serum given intrathecally. Others^{10, 23} have used this route, and have recommended it particularly when patients fail to show the expected improvement with intravenous treatment alone. In our group the patients showed little clinical improvement before the second or third day after therapy was begun.

Meningococcal Meningitis

The 12 cases of meningococcal meningitis confirmed the opinions expressed in the recent literature regarding the efficacy of sulfonamide therapy in this type of meningeal infection.^{11, 12, 20-23} Except for 2 cases the age incidence was from two months to five years. The duration of symptoms prior to admission varied from one day in 4 cases to ten days in 2 cases, averaging four days. Two patients died, the infection in these taking the form of a fulminating meningococcal septicemia. All the other patients survived, with no specific treatment other

than large doses of sulfonamides, except for one (D. C.) who also received a small amount of polyvalent antiserum.

The management of these patients was less exacting than that of those with influenzal meningitis; many of them did not show the extreme toxicity observed in the influenzal cases. For this reason fluids and medication could usually be given orally from the start, although it was often necessary to supplement the fluid intake with intravenous or subcutaneous injections. Only 1 patient in this group (A. S.) received intravenous chemotherapy,† but high blood levels, from 17 to 34 mg. per 100 cc., were obtained with oral administration. Sulfadiazine alone was used in 9 cases, and the three other sulfonamides in 1 case each. Cases were treated successfully with sulfadiazine, sulfathiazole and sulfanilamide, respectively. In the fatal case (A. S.) treated with sulfadiazine and sulfapyridine the patient actually received little of either. The sulfadiazine was given orally and not retained, and one dose of sodium sulfapyridine was given intravenously, when the patient was already in extremis. The patient in this group who was given serum was so treated because she showed evidence of an acute ethmoid sinusitis, and it was thought possible, but never proved, that this was a focus of the infection.

The 2 patients in this group who died (P. M. and A. S.), both infants, of two and nine months, respectively, had acute fulminating meningococcemia, or the Waterhouse-Friderichsen syndrome.²⁰⁻²² The onset in each case was extremely acute and the course was typically rapid. Each patient was admitted only a few hours after the first symptoms of illness, and the total duration in each case from the onset of symptoms to death was twelve hours. Blood cultures in both cases grew a meningococcus, and this organism was found on culture of the spinal fluid in one case, although the spinal fluid in both cases was negative on microscopic and chemical examination. Autopsy showed in one case complete destruction of the adrenal glands by hemorrhage; in the other there was only a small amount of adrenal hemorrhage. Treatment consisted of intravenous sulfonamide therapy, fluids, plasma and so forth and in one case adrenalin and adrenocortical extract.²³

The opposite extreme is illustrated by the case of a five-year-old boy (D. L.) admitted with possible signs of meningeal infection, a slight petechial rash and a high fever of one and a half day's duration. He was in no distress, was not toxic and complained only of general malaise and headache. The spinal fluid on admission showed nothing abnormal; the cell count was only slightly elevated, the chemical findings were normal, and the smear showed no bacteria. The patient was started on sulfadiazine, however, because of the obvious, if unproved, in-

*Rabbit serum is less likely to produce allergic reactions, and it possesses the theoretical advantage that the antibodies are contained in a smaller protein molecule than they are in horse serum, and thus diffuses more readily through the choroid plexus.²³

†At the time of writing, another patient, still in the hospital, received intravenous sodium sulfadiazine for the first twelve hours after admission, and developed a gross hematuria, which cleared up the following day, following alkalization of the urine.

fection, and by the following morning the spinal-fluid culture taken on admission had grown meningococci. Another spinal tap, done that morning, showed cloudy fluid with a marked neutrophilic reaction, but the fluid was sterile on culture. In other words, the patient had been cured within less than a day after chemotherapy had been begun.

Pneumococcal Meningitis

The 5 cases of pneumococcal meningitis indicate that this disease still has an extremely poor prognosis.^{11, 12} Of 5 patients, only 1 survived, although they all received intensive treatment. Recent figures in the literature show far lower mortality rates than this,^{12, 19, 34} but not in this age group. The age incidence varied from two to fourteen months. The patient who survived (M. H.) was the oldest of the group, and was admitted with a typical history of an acute onset of meningitis of one day's duration. There was no apparent focus of infection and no previous illness leading up to the meningitis. She was treated in much the same way as were the patients with influenzal meningitis discussed above; continuous intravenous therapy was necessary for several days, and the patient received large doses of soluble sodium sulfadiazine (3 or 4 gr. — 0.20 to 0.27 gm. — per pound of body weight a day) by this route. In addition she was given large doses of type-specific antipneumococcus rabbit serum intravenously, the dosage totaling 360,000 units, spread out over several days. Repeated Quellung tests with the patient's serum against her own organisms showed adequate antibody titer in the blood. The concentration of sulfadiazine was allowed to rise very high: on the second day after admission it was 45 mg. per 100 cc., and for the ensuing week it was still very high, gradually decreasing as the dose was decreased and the method of administration was changed from the intravenous to the oral route. Clinical improvement was slow. The temperature came down by lysis, remaining above normal for two weeks, and the first sterile spinal-fluid culture was made on the thirteenth hospital day. The patient made a complete recovery and was still free of any evidence of sequelae six months later. She never showed any signs of drug toxicity, despite the sustained high level of sulfadiazine.

An even higher level of the drug was reached in another patient in this group (M. R.) — 52 mg. per 100 cc. This patient died after twelve days of intensive treatment, and at autopsy the kidneys showed no evidence of damage due to sulfadiazine. Levels of sulfapyridine in the spinal fluid up to 50 mg. per 100 cc. have been reported and have been well tolerated.³⁵ As in the cases of influenzal meningitis, it is difficult to evaluate the benefit to the patient of these high concentrations of sulfonamide.

Of the patients in the pneumococcal group who died, 2 showed other (primary) foci of infection. In one case there was an extensive bronchopneumonia,

and in the other an acute otitis media, from which the same type pneumococcus was cultured as the one found in the spinal fluid. Of the 4 patients who died, 2 died within a day after admission, before adequate chemical or serum therapy had been given; the other 2 survived for eleven and eighteen days respectively. Positive blood cultures were obtained in 3 of the 5 cases, including the patient who survived.

No conclusions can be drawn from this group other than that the disease is so serious that the most intensive therapy is demanded. Sulfonamides have had an important part in lowering the mortality of this disease,^{11, 36, 37} but the consensus is that the combination of sulfonamide and serum therapy offers the best chance for recovery.^{35, 38-43} This is probably particularly true of the age group dealt with in this paper.

Colon-Bacillus and Salmonella Meningitis

Two other cases complete this series. One was that of a six-week-old infant with meningitis due to the colon bacillus. This patient responded well to treatment with sulfathiazole, with a maximum concentration in the blood of 2.5 mg. per 100 cc. The spinal culture became negative within a week, and the clinical course was uneventful, except for atrophy of the optic nerve, which produced blindness. Such neurologic changes are relatively common among patients who survive colon-bacillus meningitis.⁴

The other case was that of a five-week-old infant with meningitis due to a member of the *Salmonella* group.⁴⁴ These organisms are rare as a cause of meningitis,^{3, 7, 45} not more than 41 cases being reported in the literature.^{7, 45-48} The organism in this case was identified as *Salmonella oranienburg*, one of the paratyphoid C or cholerae-suis group. It is described as not normally being pathogenic for mammals,⁴⁹ and it has usually been found in birds, particularly chickens and pigeons. It has been recovered from human beings in cases of gastroenteritis^{50, 51} and food poisoning.⁴⁹ The patient came from a farm outside of Boston, but attempts to recover the organism from the livestock on the farm were unsuccessful. This organism has been identified as the cause of meningitis in one other case.^{51, 52}

The patient's course was steadily downhill. He failed to show any response to sulfathiazole,* in spite of a blood level of 8.2 mg. per 100 cc. He developed signs of blockage of the ventricular system, with a progressive increase in the head circumference despite almost daily cisternal or ventricular taps. At autopsy there was practically nothing left of the brain tissue itself, and there were large walled-off sacs of pus throughout the brain.

SUMMARY

* Twenty-eight consecutive cases of meningitis are reported, and the treatment is described. In in-

*In the past, *Salmonella* meningitis has been considered a usually fatal disease,⁴⁶ but recent reports show cures with the use of sulfonamides.^{7, 45, 47}

MEDICAL PROGRESS

NEW THEORIES CONCERNING ASTHMA

FRANCIS M. RACKEMANN, M.D.*

BOSTON

RECENTLY there came to the Massachusetts General Hospital a patient whose case illustrates so many of the problems concerned with asthma and emphysema that it will be helpful to use it as a text for the following review of the facts and theories of this disease.

The patient was an active lawyer and business man of fifty-two who through most of his life had been well except for a troublesome nasal catarrh, which continued without change in different seasons and environments. There was no history of eczema or of seasonal hay fever, and there was no asthma until the age of forty-seven. At that age, the nasal catarrh became worse and sinusitis developed. The patient began to cough at night, and his appetite fell off. He began to lose weight. He was run down and was sent to Hot Springs, Arkansas, for rest and treatment. During that visit the asthma first appeared, in a sudden sharp attack. In the five years since then it has continued through all seasons and in all places, with ups and downs perhaps but with no real letup. During this time the patient has had all manner of treatments, as will be discussed.

At the present time he has asthma and emphysema of a severe grade. The chest has a barrel shape, but there is no clubbing of the fingers. The air sacs are distended, and one can assume that many have coalesced to make larger air spaces, with consequent reduction in the surface area of the lungs. The diaphragm is low and under the fluoroscope it moves but little. The function of the lungs is greatly reduced. There are times, however, when the patient can lie back on his pillows comfortably and can walk to the toilet without trouble, but there are other times when mucus collects in the pharynx or bronchi or both and precipitates a violent attack of cough and wheezy dyspnea. This is relieved somewhat by an epinephrine spray and better by adrenalin given subcutaneously, but occasionally requires an intravenous injection of aminophyllin. It is evident that the disturbance of lung function is not constant in degree, and it is hard to believe that all these symptoms can be explained simply by the mechanical limitation of this function.

The patient is generally miserable. He is evidently frightened by his disease and is obviously apprehensive about its future developments. He has lost much weight, is very thin, and has no appe-

tite. He is unable to concentrate on anything and he does not care for reading.

What causes this disease? The wheeze suggests allergy, but it is now recognized that "all is not allergy that wheezes," and in this case, as in many of similar nature, it is not possible to demonstrate any relation between the symptoms and changes in the environment or diet. The patient has lived in different places, but he could never see that houses, rooms, mattresses or pillows made any difference to him.

One thinks of foods. Here in the hospital he was fed a diet high in calories and vitamins, with no limitation as to choice of foods, and seemed to thrive on it. Skin tests were made on three different occasions by three different physicians, and it is interesting to compare the reports. There are one or two items that appear in each of the reports, but on the whole the "foods allowed" and the "foods to be avoided" vary within considerable limits. Furthermore, diets have been arranged on the basis of these previous tests; the patient has followed each of them closely but without benefit. At one time the diet was limited to fruit juices and gelatin, with several enemas a day, and the patient said that the procedure "nearly killed" him.

Eosinophils in blood smears have reached 13 per cent and once 20 per cent of the total leukocytes, which have run to 10,000 and 12,000 per cubic millimeter. This eosinophilia is suggestive of allergy, but there is no reason to assume that allergy is its only cause.

The theory of allergy fails to explain this type of case. The onset at the age of forty-seven was late for the development of hypersensitiveness. More important is the fact that the symptoms bear no relation whatever to changes in season or environment.

Is the patient "toxic"? His voice has a nasal quality. He has trouble in the sinuses as well as in the bronchi. The sputum is considerable in amount but consists only of frothy mucus. It is not purulent. There is no fever, and the white-cell count is not elevated. The evidence of toxicity from bacterial action is not so marked as in other patients who are less miserable.

Operations on the sinuses in patients with asthma have been discussed for years. Some writers claim to have cured their patients by operation, and no doubt such good results do occur. On the other hand, other writers hold that the sinus disease is a

*Associate in medicine, Harvard Medical School; physician, Massachusetts General Hospital.

part of the picture and not the cause of it. The literature on this subject has been reviewed well and competely by Hansel.¹ The incidence of asthma in nasal and paranasal sinus disease, according to him, varies from 3 to 22 per cent, and that of gross nasal disease in asthma varies from 20 to 90 per cent. The results of rhinologic operative treatment of asthma show "cures" (the word is always quoted) in 5 to 20 per cent of the cases, although two of the papers cited by Hansel gave higher figures for small series of patients. Meantime the figures for "good results" additional to the "cures" vary from 10 to 80 per cent. There are, however, a large number of patients with a history of previous operations of various kinds and yet without benefit from them.

Weille² in 1933 made a complete study of 40 patients with sinus disease and asthma. They had been selected for operation with the greatest care and were followed for at least two years after operation. Only 4 patients were made free of their asthma, but 8 others were markedly improved and 6 obtained moderate improvement. Eighteen cases, however, were failures, except that 7 of them were cured or improved for a few months. More recently Cooke,³ in discussing the allergy problem, mentioned that he and Grove had treated a large number of patients by sinus operation. Of those with adequate sinus surgery, only 8 per cent remained unimproved, whereas of those with incomplete surgery, 64 per cent were unimproved. The difference is impressive.

The paranasal sinuses consist of collections of bony cavities, some small and tucked away in remote places. The difficulty of evacuating the contents of every one of them is understandable. One trouble with the theory that good results follow only those operations that are adequate is that in a number of cases the asthma has been cured or improved when no operation at all was performed, or when only one side of the nose was treated — and these patients had aside from asthma all the earmarks of chronic sinus disease. Whether there is a special way of performing sinus surgery — whether, for example, the good result depends on the chance excision of a particular sensitive spot, or perhaps of a certain nerve ending — is a question not yet answered. In recent months the practice at the Allergy Clinic of the Massachusetts General Hospital has been to operate only when the condition of the sinuses is so bad that operation is indicated without regard to the asthma. As patients who have been operated on either outside or in our clinic are observed, it becomes more and more clear that sinus surgery does not often effect a cure.

The patient described above, for example, has already had three operations. The first was for the removal of polyps. The second was performed in March, 1942, in the fourth year of the asthma. On the morning after it, his wife went to see him in the hospital and found him unconscious and cyanotic. Fortunately meningitis was recognized and treated

at once with large doses of sulfonamide drugs, and the patient recovered. He was in the hospital for three months. Whether the so-called "polyp" that the surgeon saw was a meningocele with direct connection to the cranial cavity, or whether the curet was pushed through an extra thin plate of bone, is hard to say; the accident shows well that extensive sinus surgery can be dangerous. The asthma cleared during this emergency, but it returned before the patient left the hospital, and the next winter he went back to Arizona, where the asthma persisted but he gained a little strength.

In June, 1943, emphysema was marked and asthma was troublesome. Epinephrine by hypodermic injection gave some relief. Aminophyllin by mouth (3 gr. three times a day) seemed helpful, but aminophyllin by vein (in an ampoule containing $3\frac{3}{4}$ gr. dissolved in 10 cc. of normal saline solution) was at times necessary. The sinuses were cloudy as shown by x-ray and another operation was performed. Nasal polyps were removed and windows were cut on each side between the nasal cavity and the antrum. There was a little improvement for a week or so but the asthma then returned as before. The latest x-ray films still show thickening of all the sinus membranes, but it is clear that no one wishes to operate again on the nose or sinuses.

There is no report that deals directly with bad teeth as a cause of asthma, although hundreds, if not thousands, of teeth have been removed in the hope that the cause of trouble would be removed with them. In several cases at the Massachusetts General Hospital abscessed teeth have been removed, but obviously without benefit. In a few cases, however, the results have been almost miraculous, so that chronic asthma with a short duration and a severe course, as in the case here described, has been greatly improved when abscessed teeth were found and extracted. In this case x-ray films did show small abscesses around several of the teeth, and six of these were extracted. There was a reaction, consisting of a moderate increase in the asthma on one day.

Has this patient some organic lesion in the bronchial tree that is causing his asthma? This question should be asked in all cases, for carcinoma and other tumors of the bronchial wall may occur. I have seen several such cases. Sarcoid disease and tuberculosis have also been obvious, with lesions on the bronchial mucosa producing local irritation in rare cases. A syphilitic gumma was found in another case. In each of these, however, the lesion was shown by x-ray. In the present case, the x-ray films are remarkably free of any evidence of a local process.

The nervousness can be easily explained as a result of the disease rather than as a cause of it. When later in the hospital stay the symptoms improved, the nervousness also subsided. In his recent book *The Borderlands of Psychiatry*, Cobb⁴ shows most wisely that disturbances of the psychic are not to

be separated sharply from those of the general bodily function. In diseases of every kind and in almost every patient, some evidence of psychic abnormality can be found. Psychic disturbances are to be expected whenever symptoms are severe, but in most cases, as in this one, an explanation of the trouble on the basis of nervousness alone is not sufficient.

So far, no one of the ordinary theories concerning the cause and nature of asthma applies to this case, and the same statement can be made for many other cases in the same group. One has to think of some physiologic disturbance the nature of which is so far unknown. Albright⁵ says, "Obscure diseases usually are not made lucid by incriminating the endocrines." Nevertheless in the present case, as in others like it, there is some evidence of abnormality in the function of the adrenal glands.

First, however, a word must be said about epinephrine, the active secretion of the adrenal medulla. Adrenalin relieves asthma. It relieves this patient at times, but not so well as it relieves the more typical extrinsic cases. Has the patient a deficiency of adrenal secretion, or has he perhaps lost the ability to respond to it in the normal fashion? Bloor and Bullen^{6,7} have described a chemical method for determining epinephrine in the blood. Normally in dogs and human beings, the presence of epinephrine cannot be demonstrated in the peripheral venous blood. When various solutions of epinephrine were injected intravenously and in large quantities (as much as 1 cc. of a 1:1000 dilution) into a 30-pound dog, 25 per cent was recovered in one minute, 21 per cent in five minutes, and 14 per cent in twenty minutes after the injection; the remaining 40 per cent was lost.

Koref and Rivera,⁸ also using a colorimetric method, attempted to study the epinephrine content of the adrenal glands after the administration of histamine and of peptone and after anaphylactic shock, but in their preliminary work the values for normal animals and man varied widely, with a tendency toward lower quantities in older people. Cohen, Rudolph, Wasserman and Rogoff⁹ found no significant alteration in the rate of secretion of epinephrine from the adrenal glands of sensitized dogs before and during anaphylactic shock from horse serum. There are no studies of adrenaline in the blood in asthma, and it seems unlikely that such a study would be profitable. The physiologic activity of epinephrine is so great that one can ascribe its therapeutic effect to a direct stimulation of the sympathetic nervous system rather than to an indirect replacement of the hypothetical insufficiency of the secretion of the adrenal medulla.

The adrenal cortex is quite another matter. Three functions of it have so far been recognized. The first is concerned with the metabolism of salt and water. This is markedly deficient in Addison's disease and can be improved by treatment with desoxycorticosterone. The second is concerned with the sugar

metabolism and influences the formation of sugar in the body from the breakdown of protein substances. This function is expressed by Compound E of Kendall,¹⁰ which is described as 17-hydroxy, 11-dehydrocorticosterone. Albright¹¹ calls it the S hormone (see below). The third function is concerned with nitrogen, with growth and with the building of protein. It can be estimated in part by the determination of the amount of 17-ketosteroids excreted in the urine. Albright calls it the N hormone.

There are a number of clinical observations in asthma that suggest disturbances in the salt-and-water metabolism. Potassium iodide is of benefit, supposedly because it stimulates the mucous glands in the bronchi. Bloom¹² has recommended potassium chloride for hay fever. Does the potassium radical have any other action? For some patients I have prescribed teaspoonful doses of bicarbonate of soda after each meal, to be taken with the potassium iodide, and some patients like it. To others I have given hydrochloric or nitrohydrochloric acid, as advised originally by Beckinan,¹³ and some of them like this. When asthma is extremely severe and the patient is in great distress, the intravenous injection of 1500 cc. of normal saline solution containing 5 per cent glucose is usually effective. The dose provides about 14 gm. of sodium chloride and about 45 gm. of sugar; it is sometimes repeated in six to twelve hours. When patients with severe asthma develop cor pulmonale with edema of the extremities, the asthmatic wheeze usually ceases. Incidentally, the fact that asthma clears during fever and during jaundice is also interesting. These clinical observations suggest that the administration of extra salt does good. There are several papers that touch on this subject, but they give the opposite impression—namely, that extra salt does harm.

In 1940, Stoesser and Cook¹⁴ observed that the feeding of large amounts of dextrose to children with asthma helped them, but if large amounts of sodium chloride were given at the same time, the total effect was not so good. In another paper, the same authors¹⁵ described a new experiment. Children were placed on a diet low in salt. They lost weight and when they were dehydrated fever therapy helped the asthma. If, however, sodium chloride was fed, water was again retained, and when the salt content of the serum returned to normal, fever therapy no longer relieved the asthma. Pitressin was tried because this hormone from the posterior pituitary gland has an antidiuretic action. It can cause a retention of water without the retention of sodium chloride at the same time. A child was placed on the same low-salt diet and continued to have asthma. On the eighth day Pitressin was given and the water intake was considerably increased. After twenty-four hours the asthma cleared, and in thirty-six hours the patient had gained 1.5 kilograms in weight. The treatment was then stopped; the patient excreted 2000 cc. of urine in twelve hours, but the

asthma did not return. After a few months, however, when the sodium chloride content became high, asthma again appeared. Another child also continued to have asthma on a low-salt intake and was benefited by Pitressin. During the antidiuretic phase caused by the drug, water was retained and the asthma cleared, but later when the Pitressin was withdrawn and diuresis occurred, the wheezing recurred. In observations made by Stoesser and Cook on 20 children, in 18 the asthma improved during the phase of water retention, and with it there was a drop in the concentration of sodium, potassium and chloride in the serum. Data on the actual excretion of electrolytes in the urine are not given, but other studies indicate that salt is lost to the body in the more concentrated urine of the antidiuretic phase of the effect of Pitressin. The authors conclude, "It is apparent that bronchial asthma can be ameliorated even in the presence of excessive hydration if there is an associated depletion of sodium chloride." Donovan and Harsh¹⁶ compared the concentration of serum sodium in normal and in allergic persons and found the figures to be about the same. In pregnancy they were a little lower than the average, suggesting that asthma is less severe during pregnancy because of the depletion of electrolytes.

Of greater interest is the paper by Sheldon, Howes and Stuart.¹⁷ They were fortunate in having 5 patients in whom asthma could be started and stopped by exposure to specific foods or dusts. These patients were placed on constant diets with a fixed water intake and the allergenic food was then fed. During the attack that ensued there was a marked loss of water and sodium, so much so that the sodium excreted in the urine was increased to twice the quantity eliminated during the nonasthmatic period. During the asthma the total quantity of sodium excreted in the urine in twenty-four hours was 3 to 5 gm. more than the amounts ingested. In the discussion of this paper, it was pointed out that in serum disease, as well as in pneumonia and other diseases producing fever, the body does not eliminate salt and water; the contrast between the findings of Sheldon in asthma and the findings in pneumonia is interesting. This difference in the salt metabolism of the two conditions is hard to explain, but the marked loss of water and sodium during the attack of asthma that Sheldon describes fits well with our own clinical observations, and makes the relief of symptoms by replacing this loss understandable.

Loeb¹⁸ has described the relation between the adrenal glands and salt metabolism. In Addison's disease, the sodium content of the blood is low. A diet without sodium may bring on the symptoms of Addison's disease (adrenal insufficiency), which are relieved when sodium is again given. When the adrenal glands are removed from an animal, there is a tremendous excretion of sodium in the urine, and during this process potassium is retained in the body. The contrast between the loss of sodium and the

retention of potassium is striking. In diabetes and in the ketosis of starvation, on the other hand, the loss of base entails a loss of both sodium and potassium at the same time. When adrenocortical extract in the form of desoxycorticosterone acetate is fed to adrenalectomized animals, the effect is the same as that of giving large quantities of salt (sodium) and water, except that the improvement is more striking. The administration of desoxycorticosterone or its esters to patients with Addison's disease causes a striking retention of salt and water; one of Loeb's patients gained 11 kilograms in the first ten days of such treatment. The concentration of potassium in the blood falls as that of sodium rises.

This treatment, however, is not without danger. When desoxycorticosterone acetate (Doca) was fed to normal dogs, they developed in ten days a sort of diabetes insipidus. They drank water avidly, sometimes 3000 to 5000 cc. a day, but this stopped when the drug was omitted. If continued, however, it brought on a curious weakness of the muscles, and if it was still continued, the animals died in ten to fourteen days. If they were given a 0.15 per cent solution of potassium chloride instead of tap water, the muscle weakness did not occur, although the diabetes insipidus was unaffected. After death the skeletal muscles showed a large amount of sodium and little potassium, and it is clear that the feeding of potassium tended to prevent the decrease in cellular potassium without, however, making any change in the high blood sodium. Evidently the diabetes insipidus depends on the high concentration of sodium in the serum and in the extracellular fluid, whereas the muscle weakness depends on the loss of potassium in the cells and its replacement by sodium. Desoxycorticosterone acetate has a direct effect on the metabolism of electrolytes, but none on that of sugar or nitrogen. Thorn and his associates¹⁹ have shown that other and closely related steroids are concerned with these other processes.

The treatment of asthma with extract of the adrenal cortex has been attempted. In 1936, Wilmer and Miller²⁰ treated patients with an extract of whole adrenal cortex (Eschatin) and claimed results that were spectacular in some cases, although disappointing in others. Fincman²¹ treated 4 patients with Eschatin when their asthma was stationary. One showed marked, 1 moderate and 1 only slight improvement, but in 3 patients there was a decided increase in strength and appetite, with a gain in weight. Nothing is said about the factors of salt and water. Cohen and Rudolph²² used another product of the adrenal cortex (Interrnalin) and found no effect in 4 cases. More recently, Dragstedt, Mills and Mead²³ found that a prior administration of adrenocortical extract to sensitized dogs did not prevent anaphylactic shock but tended to diminish the severity of the reaction. One wonders about the so-called "nonspecific effect" of the doses. In 1938, Prickman and Koelsche²⁴ treated 16 asthmatic pa-

tients with Cortin injected intravenously, and the treatment was supplemented by excessive amounts of sodium chloride given by mouth. Little or no specific benefit was observed.

More recently, the effect of feeding extra salt has been tried on debilitated patients in the Allergy Clinic at the Massachusetts General Hospital. Patients with asthma have been given up to 12 gm. additional of sodium chloride by mouth each day. In some cases, particularly when the patient is thin and in poor general condition, the extra salt has had a good effect, but in others, especially in those who are well nourished and in good condition, no benefit has been obtained. It goes without saying that in this type of experimentation clinical results without actual measure of the effect of treatment mean little. Nevertheless, the results are suggestive. In the case reported herein the chloride content of the fasting blood was 95 milliequiv. per liter in place of the normal figure of 105 milliequiv. The patient felt a little better under the salt treatment.

Another theory about asthma is interesting. Periarthritis nodosa is a pathologic lesion that is occasionally found in patients with severe asthma. In the series of 50 fatal cases reported by Rackemann and Mallory²⁵ in 1940, periarthritis nodosa was found in 5 cases, a high percentage. In 1942, Rich²⁶ reported that the lesions of periarthritis nodosa could be observed in certain patients who died of some acute infection but had serum disease at the same time. Later he and Gregory²⁷ demonstrated that the same results can be produced in rabbits by treating the animals in various ways with foreign serum. This work is an important advance. It shows that periarthritis nodosa is not a disease entity but is merely a part of a complex process, and that the lesion can be produced by methods similar to those used in producing serum disease or the Arthus phenomenon.

During 1943 Selye and Pentz²⁸ presented new data that are likewise of primary importance. They showed that the lesions of periarthritis nodosa, of malignant hypertension and of rheumatic arthritis in rabbits are similar and that each of them can be produced by treatment not only with foreign serum but with foreign proteins of other sorts, as well as by bacterial products. Also, treatment of the animals with desoxycorticosterone acetate together with a large intake of salt produced the lesions of periarthritis nodosa. In discussing their results these writers point out that in each case the lesions depend on treatment that is drastic and produces a profound disturbance in the animal, and they propose the interesting theory that the lesion results from nothing more than the "alarm reaction," a term which was used first by Selye²⁹ in 1936 to indicate the shocklike syndrome that develops from any severe insult to the body. It perhaps depends on excessive secretion of adrenal hormones, but it now appears that treatment with serum, other foreign

proteins or bacteria serves to elicit the alarm reaction in a purely nonspecific manner, and that the development of periarthritis nodosa is merely the response to this severe treatment. Not much is said by Selye about the symptoms displayed by his animals. Asthma is not mentioned, and perhaps it is too much to consider his observations as having any relation to the asthma problem. On the other hand, they are, like the salt experiments, suggestive.

The patient here described suffers from a sort of exhaustion. He has lost weight, the blood pressure is low (110 systolic, 80 diastolic), the pulse is rapid (90 to 100), and the fasting blood sugar is low (73 and 85 mg. per 100 cc. on different days). The glucose tolerance, however, shows a normal curve. The blood protein is 6.6 gm. per 100 cc. In twenty-four hours he excreted only 5.5 mg. of 17-ketosteroids in the urine, whereas the normal man excretes about 15 mg. He is obviously depleted in various ways. This condition suggests a deficiency of the adrenal cortex. Obviously, there are many difficulties in the way of proving that this idea has significance in the asthma problem as a whole. Selye defined the alarm reaction as "the sum of all biological phenomena elicited by sudden exposure to stimuli to which the organism is quantitatively or qualitatively not adapted." Biologic phenomena develop in asthma of every variety, but the very fact that some evidence is in favor of the theory and some against it shows that the alarm reaction by itself has little to do with allergy or with asthmatic attacks that occur as isolated episodes in persons who are otherwise in good general health. At least the consequences of the alarm reaction are not important in average or ordinary cases. When, however, the attacks are repeated or when they become successive and confluent, as in this case, there may be evidence of a general disturbance of severe grade, which, as here, causes symptoms of another kind that are additional to the difficult breathing of asthma. These symptoms are separate from the asthma, even though they are caused by it in the first instance.

Selye's concept of the alarm reaction is most interesting. He shows that the disturbance can develop from injuries of many kinds and without any one exciting cause. The evidence of adrenal activity in the shock stage is followed by other evidence of adrenal exhaustion in the countershock stage, and one might describe this patient as being always in the countershock, depressed phase of the alarm reaction. Albright³¹ has pointed out that the hypertrophy of the adrenal cortex in the alarm reaction is associated with an initial release of the adrenal hormone that controls the production of sugar from protein breakdown (gluconeogenesis), — the S hormone, — and also of the other hormone concerned with the building of protein tissue, — the N hormone, — but that this change is followed by an overproduction of S hormone and an underproduction of N hormone. After injuries the

obilization of energy and the conservation of aterial for general repair are beneficial. On the her hand, if the excess of S hormone and the minution of N hormone are continued too long, generalized debility results. The negative nitrogen alances observed during the alarm reaction, even the presence of an adequate protein intake, come explainable on the basis of a decreased protein synthesis rather than of an increased protein breakdown. The observations made so far in the resent case fit such a theory well, and the conception as a whole should stimulate greater interest in the theory that certain forms of the symptom omplex that is called asthma may be after all merely one expression of a fairly general and diffuse hysiologic disturbance. The treatment of this disturbance by the use of appropriate hormone-like substances that have been developed from investigations based on these theoretical considerations may be expected.

Once more, it is clear that "all is not allergy that heezes."

CASE 30101

PRESENTATION OF CASE

A thirty-seven-year-old trainman entered the hospital because of upper abdominal and periumbilical pain.

The patient was in apparent good health until two or three years before entry, when he noted mild attacks of sharp stabbing pain in the upper abdomen. The pain usually started above the umbilicus and then radiated to the lower part of the chest, through to the back, and down to the lower abdomen. These attacks came on any time of the day without relation to meals or activity, and lasted from a few minutes to two or three hours. They did not incapacitate him. About six months prior to admission the attacks became more frequent and the pain quite severe. They were accompanied by an intense desire for food, which disappeared as soon as he had eaten a few mouthfuls. He developed constipation without any change in the color or consistence of the stools. These symptoms progressed until admission. There were no chills, fever, jaundice, nausea, vomiting or clay-colored or tarry stools. He had lost 20 pounds in weight in three months. He seemed to be constantly hungry.

Physical examination showed a thin, rather pale man who looked uncomfortable but was not in distress. The heart and lungs were normal. Marked tenderness was elicited in the epigastrium, more on the right, with spasm and a suggestion of an indefinite epigastric mass.

The temperature was 99.6°F., the pulse 90, and the respirations 20. The blood pressure was 120 systolic, 90 diastolic.

Examination of the blood showed a red-cell count of 5,000,000, with 80 per cent hemoglobin. The white-cell count was 8900. The urine was negative. The blood sugar was 123 mg. per 100 cc., the non-protein nitrogen 23 mg., and the blood protein 7.2 gm. The chloride was 100.2 milliequiv. per liter. A glucose tolerance test revealed a fasting sugar of 145 mg. per 100 cc.; at the end of the first hour the blood sugar was 193 mg., at two hours 253 mg., and at three hours 235 mg. The serum amylase was

*On leave of absence.

normal. A blood Hinton test was negative. Graham test was essentially negative.

A gastrointestinal series showed a normal esophagus and stomach. The antrum of the stomach was displaced upward and anteriorly by a large mass that seemed to fit into and widen the duodenal loop (Fig. 1). The mass compressed the duodenum but did not obstruct it. Numerous flecky areas of calcification were seen in the mass. Some of these extended farther up into the left upper quadrant. The mucosal pattern of the duodenum was normal.

On the twelfth hospital day a laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. OLIVER COPE: A mass in the region of head of the pancreas is described in the x-ray report. Careful examination of the x-ray films is going to be important in arriving at a final diagnosis, but before seeing the films I shall make certain comments.

The patient's symptoms do not offer a clue as to the nature of the disease. Any mass in the region described could cause such pain. Hunger relieved by food is also not specific of any lesion. The absence of change in the character of the stools suggests that there was no blockage of the pancreatic duct, because if pancreatic lipase is excluded from the upper intestine, the stools usually are grossly fatty. The absence of jaundice excludes blockage of the common bile duct.

The laboratory examination is of some help for points to disease of the pancreas. The important positive finding is a diabetic tendency, the glucose tolerance being decreased. This tendency suggests destruction of islet-cell tissue. Such destruction is unusual but can occur as the result of long-standing inflammation.

The fever on entry apparently did not continue and the process presumably was not infectious. The normal blood amylase does not exclude an inflammatory process: the characteristic finding of a pancreatitis is an elevated blood amylase, but activity of this enzyme has usually returned to normal after the first week of the disease and remains normal during the chronic and late stages of the disease. An elevated blood amylase occurs for a brief period immediately following an obstruction of the pancreatic duct, but does not follow slow, delayed closure of the duct. Complete obstruction of the pancreatic duct is therefore excluded by this normal finding, and one must look for a chronic inflammatory change in the body or wall of the pancreas without demonstrable alteration in the amylolytic power of the blood.

Before we go farther I should like to see the x-ray films. What does the x-ray department mean by an "essentially negative" Graham test?

DR. LAURENCE L. ROBBINS: I think what was meant by the interpretation of "essentially negative" is the lack of evidence of gallstones and the fact that

The gall bladder appears to function well in the Graham test. It is displaced. That is why "essentially" was put in the report.

DR. COPE: It also says that the calcified areas were seen in the region of the mass. Is the mass visible on the films?

DR. ROBBINS: The gastrointestinal examination shows a pressure defect on the greater curvature side of the antrum and in the pyloric region, with definite

determined from the position of the ligament of Treitz.

DR. COPE: Do the areas of calcification retain a constant position in the two examinations?

DR. ROBBINS: Yes.

DR. COPE: Is there no evidence of shift?

DR. ROBBINS: No.

DR. COPE: The first question that comes to mind is, Are these areas of calcification pancreatic stones?

FIGURE 1. Photomicrograph of the Krukenberg Tumor.

displacement of the duodenal cap and second portion to the right, and numerous flecks of calcification in the region of the mass. The mass appears to be fairly well localized to the head and body of the pancreas. The duodenum in the region of the ligament of Treitz does not appear to be displaced appreciably. There is no evidence of invasion of the mucosa of the duodenum.

DR. COPE: "Some of these extended farther up into the left upper quadrant." What does that mean?

DR. ROBBINS: There are areas of calcification in the upper quadrant, but no appreciable enlargement of that portion of the pancreas so far as can be

I think Dr. Robbins will answer "No." I suspect that they are not pancreatic stones, even though the area of distribution involves the pancreas, because the area involves an enlarged pancreas. It is enlarged beyond that which I would suppose could be associated with calculi in the duct of the pancreas. Perhaps these little objects that are in the region of the tail of the pancreas could be explained as stones, but probably not those in the head of the pancreas. Pancreatic stones are rare and perhaps they do occur within the ducts in the presence of an enlargement of the pancreas. I have never seen this. I tend to exclude stones, however, as the primary lesion in

this case on the basis of the circumferential arrangement or pattern. Whether there were stones out in the tail of the pancreas I do not know.

Will Dr. Robbins comment on that?

DR. ROBBINS: Those in the tail might be stones, but the areas of calcification in the region of the head are quite linear and do not have the typical appearance of the few cases of pancreatic lithiasis that I have seen.

DR. COPE: I shall go back one step to say that I think this mass visualized by x-ray with the areas of calcification adequately explains the patient's symptoms and also, one could imagine, the decreased glucose tolerance or inadequate production of insulin. The problem therefore resolves itself into trying to judge the nature of the lesion giving rise to this x-ray picture. Stones can produce a diabetes because there is an associated fibrosis of the pancreas, which results from chronic blockage of the pancreatic ducts, and that fibrosis may go on to cell destruction of the islets with a resultant inadequate amount of insulin. The occurrence of diabetes following stones and fibrosis has been reported. I have never seen diabetes come on following tumor of the pancreas and this seems unusual to me. Yet I suppose it could occur with any slowly growing, fibrosing, sclerosing lesion. Ordinarily if there is a tumor or a cyst that arises in the head of the pancreas and is large enough to block off the duct of the pancreas, there is an atrophy and some sclerosis of the acinar tissues distal to the lesion. But there is usually adequate islet-cell tissue for normal insulin formation.

Did this tumor involve the entire pancreas? No, it did not. Apparently it involved the head, but there is also evidence of some change in the tail. Again, I think this is consistent with the picture. What could it have been if it was not stone in the pancreatic duct? It may have been any one of a large variety of conditions. The commonest are simple cysts and tumors. It is surprising that this man had not had any jaundice, but I suppose the reason is that the distortion of the duodenum was such as to allow free drainage of the common bile duct into the duodenum. The ampulla was probably above the area of pressure. The collapse of the gall bladder in the Graham test bears out the free drainage into the duodenum. Free bile drainage does not exclude obstruction of the pancreatic duct, but a cyst of this size could not be expected from simple obstruction of a pancreatic duct.

The mass could be a papillary cyst arising in a papillary adenoma or it could be one of the simple cysts. A dermoid has to be considered for they occur in the pancreas, but I do not believe that these areas of calcification are the typical markings one would expect in a dermoid. Therefore I shall assume that the calcification had occurred in areas of the cyst or tumor in which necrosis had accompanied the progressive, slow growth of the lesion. Because the calcification points to slow growth I shall assume

that the mass was not malignant and I believe that it was either a cyst, simple or papillary, or a cystic tumor, — rather than a solid tumor that had given rise to obstruction of the pancreatic ducts, — probably with some fibrosis and secondary calcification and, finally, with decreased insulin production.

DR. CHESTER M. JONES: I should like to ask whether prolonged partial obstruction of the pancreatic duct tends to stone formation. It is a rare condition. I have a hazy idea of pancreatic calculus. The diagnosis is usually by exclusion, and we are very apt to be wrong when we make it. Do you know about the formation of stones, Dr. Cope?

DR. COPE: I have no knowledge. I am saying fibrosis and stone from obstruction on a hunch. There seem to be two configurations in the x-ray film, a circular tumor and something behind in the tail. Stone formation is a pure guess. In dog fibrosis regularly follows ligation of the pancreatic ducts.

CLINICAL DIAGNOSIS

Pancreatic cyst.

DR. COPE'S DIAGNOSIS

Pancreatic cyst or cystic tumor with degeneration and calcification (nonmalignant).

ANATOMICAL DIAGNOSIS

Pancreatic cyst.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: I am sorry I, Arthur W. Allen is not here to tell you his operative findings. He found a large "cystic tumefaction," he called it, including the entire head of the pancreas and extending down the midline to the left. It was hard in some areas, but felt definitely cystic. I put a needle into it and withdrew 30 cc. of cloudy, thin, gray fluid. Small particles could be seen floating in the fluid, which he interpreted as flecks of calcified material. He then did another aspiration and obtained 90 cc. He thought that resection would be too great an undertaking at that time and merely did a cholecystostomy. He took a biopsy of the pancreas, on which we were able to report on chronic pancreatitis. There were large areas of lymphocytic infiltration but no evidence of tumor.

The patient went home, but came back three or four months later with a history of pain in the right upper quadrant. At that time Dr. Allen re-explored the abdomen and again aspirated the cyst, recovering over 500 cc. of thin, yellow-brown fluid. The cyst seemed fairly movable and a resection of the head and part of the body of the pancreas and surrounding duodenum was performed. A catheter was introduced into the cut end of the common duct, and this was brought through the jejunum to come out through a small jejunostomy; then a jejunocholecystostomy was performed. A gastroenteros-

tomy was done, after which a fine catheter was placed in the cut end of the pancreatic duct and the whole cut end of pancreas implanted in the jejunum below the gastroenterostomy. This catheter was brought out through the wall of the jejunum by a small jejunostomy. A third jejunostomy for feeding was placed below the others, and all three tubes were led out through a separate stab wound in the left abdominal wall. After this a cholecystostomy was done.

Here is a photograph of the cyst, which measured 12 by 9 by 7 cm. (Fig. 2). It had a thick fibrous wall with no lining epithelium that we could make out. When received, it contained about 200 cc. of

such, it has to be extensive chronic pancreatitis, destroying practically the whole pancreas, before the patient develops diabetes. I think that is nearly always correct.

DR. CASTLEMAN: We believed that the piece removed at the first operation, which showed chronic pancreatitis, may well have been due to pressure of the cyst on neighboring parenchyma. The tail of the pancreas may have had atrophic acinar tissue from the pressure on the pancreatic duct itself.

DR. COPE: But ordinarily that is not associated with atrophy of the islet-cell tissue.

DR. JONES: The number of cases observed clinically where there has been obstruction to the flow

FIGURE 2.

clotted blood. Although most of the lining was smooth, there were many irregular knob-like projections up to 0.5 cm. in diameter composed of old organized blood clot, many of which were hard and gritty and were undoubtedly the areas of calcification seen on the x-ray films.

DR. COPE: It was not malignant?

DR. CASTLEMAN: It was not malignant, and not of the papillary cystadenoma type. It was a simple cyst, the etiology of which is still unknown. I believe some would call it a pseudocyst resulting from previous areas of necrosis in the pancreas, rather than a cyst due primarily to obstruction of the duct. I do not believe a cyst would reach this size from mere obstruction to the duct.

DR. COPE: Was Dr. Allen able to visualize the tail of the pancreas? Was that fibrosed?

DR. CASTLEMAN: He did not mention it.

DR. COPE: In the cases that we have seen on the surgical service, it was rare to find such a benign localized lesion associated with a diabetic tendency and with the tail of the pancreas uninvolved. Is that your experience, Dr. Jones?

DR. JONES: I should think so. If it is chronic pancreatitis that the pathologist can recognize as

of pancreatic juice and an atrophic process that results in diabetes are extremely few.

DR. REED HARWOOD: I talked with the patient after the operation and it turned out that he had a family history of diabetes — a brother with severe diabetes. I have no way of knowing whether the pancreatic cyst brought on the diabetes or whether he had diabetes before the cyst developed.

DR. COPE: It is a mild diabetes?

DR. HARWOOD: Yes, extremely mild. At the present time he is getting 8 units of insulin, and sometimes he is sugar free.

DR. CASTLEMAN: It is now four weeks since the operation and the patient seems to be doing well.

CASE 30102

PRESENTATION OF CASE

A fifty-three-year-old Lithuanian machinist was admitted to the hospital because of cough, orthopnea and swelling of the ankles.

Except for slight dyspnea on exertion, the patient was well, and engaged in active work, until about eight weeks before entry. He then developed a

fairly severe dry cough. Three, or four days after this there was sudden onset of pain in the left side over the lower ribs. The pain was intensified by cough on deep inspiration. The patient had no fever or chills. Because of persistence of the cough, a physician referred him to a metropolitan hospital for a roentgenogram of the chest. The film was said to show "pleurisy on the left." Soon after this, pain developed in the right side that was similar to that previously suffered on the left. The patient then entered a nursing home for a stay of about a month. In the first days of this hospitalization he had no fever, but later the temperature rose to 102°F. and he was put to bed for two weeks, the diagnosis being "double pneumonia"; during that time, however, he felt well. After another week in the nursing home, when he was allowed to be out of bed, he was discharged. At that time, a week before entry, there was increase in the patient's usually slight exertional dyspnea. There was swelling of the ankles, and reappearance of persistent cough. The patient had paroxysmal difficulty in breathing at night. These symptoms progressed rapidly.

No significant past history could be obtained.

Physical examination showed a man sitting up in bed, with rapid and embarrassed respirations. The fingers were clubbed, and the nail beds "floating." The veins of the neck were engorged, and the fundi showed slight venous congestion. The feet and ankles showed pitting edema. The heart was markedly enlarged to the left, extending 12 cm. to the left of the midsternal line. There was gallop rhythm, and the sounds were of poor quality. A diastolic thrill was palpable at the apex. There were a loud apical systolic and probable diastolic murmur, a systolic murmur in the aortic area, and an early high-pitched diastolic murmur along the left sternal border in the third interspace. The pulse was Corrigan in type. Moist rales were heard over both pulmonary bases, up to the level of the spines of the scapulas. The liver edge was felt three or four fingerbreadths, and the spleen two fingerbreadths, below the costal margin. Free abdominal fluid was not evident.

The temperature was 101°F., the pulse 120, and the respirations 24. The blood pressure was 140 systolic, 40 diastolic.

Examination of the urine was negative. The blood showed a red-cell count of 4,100,000, with 10 gm. hemoglobin, and a white-cell count of 7000, with a normal differential. The nonprotein nitrogen was 23 mg. per 100 cc., the serum protein 7.3 gm. The sedimentation rate was 1.6 mm. per minute. Thirteen blood cultures were negative. The Hinton reaction was positive on four examinations; the Wassermann reaction was twice negative, and twice doubtful or unsatisfactory.

An electrocardiogram showed probable digitalis effect.

A roentgenogram of the chest showed the heart to be enlarged, particularly in the region of the left

ventricle. The aorta was not remarkable. The hilar vessels were dilated and fuzzy in outline. Both costophrenic angles were obliterated. Oblique and lateral views showed slight enlargement of the left auricle.

The patient was treated with full doses of digitalis and mercurial diuretics, and was given sedation and fluid restrictions. He lost fluid satisfactorily, and there was some clearing of the chest. The temperature, however, continued to fluctuate daily between 98 and 101°F., the pulse and respirations remaining somewhat more rapid than normal.

After three weeks in the hospital without essential progress, the patient was given massive doses of aspirin, to which there was no significant response. At about that time, occasional granular and hyaline casts and red cells began to appear in the urine. Eight weeks after admission, a course of sulfadiazine was given, a blood level of 16.7 mg. per 100 cc. being attained. The patient's temperature continued as before. There was progressive weakness, and two months after entry increasingly frequent episodes of severe nocturnal dyspnea began to occur, during which the physical signs of pulmonary edema were evident.

In the eleventh hospital week the patient expired, failing to respond to oxygen, morphine and tourniquets. There was a terminal elevation of temperature to 105°F.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR J. LINENTHAL: In the discussion of this case there are two main questions to be considered: first, the nature of the cardiac disease that led to congestive heart failure and death, and second, the nature of some other process that appeared to be present, the predominating manifestation of which was continuous fever of about four months' duration.

Regarding the heart disease, the problem is mainly one of distinguishing between the two important possibilities: rheumatic heart disease and syphilitic heart disease, either one of which might give rise to aortic regurgitation, which was the dominant, if not the only, valvular lesion present. Information concerning this differentiation may be obtained from the clinical picture, the physical examination, the x-ray examination and the laboratory findings.

The most striking features of the clinical picture were the suddenness of the onset and the rapidity of the progression of the picture of cardiac failure. This is suggestive of syphilitic heart disease, which frequently runs such a rapid course, rather than rheumatic heart disease, in which the course is almost always a chronic and prolonged one. Furthermore, at the age of fifty-three a first attack of congestive failure suggests syphilitic rather than rheumatic etiology.

Physical examination gave definite evidence of aortic regurgitation: a diastolic murmur along the left sternal margin, a Corrigan pulse and a blood pressure of 140 systolic, 40 diastolic. There was no evidence of aortic stenosis to point to rheumatic disease: there was only a systolic murmur in the aortic area, the transmission of which we do not know, there was no thrill, and there is no mention of abnormal aortic second sound.

The physical findings at the apex are difficult to evaluate. There is said to have been a "probable diastolic murmur," which could have been a transmitted murmur from the aortic area, an Austin-Flint murmur, or the murmur of mitral stenosis. There is said to have been a diastolic thrill at the apex. The exact significance of this is questionable in the absence of a definite diastolic murmur. Ordinarily this would be indicative of mitral stenosis. An apical systolic murmur can represent organic mitral regurgitation associated with rheumatic disease of the mitral valve, or can be the functional murmur of mitral regurgitation secondary to the left ventricular enlargement of aortic regurgitation. This last murmur is therefore of no differential help.

Thus the physical findings showed definite organic disease of the aortic valve, with aortic regurgitation, but in all probability no organic disease of the mitral valve. These findings are somewhat suggestive of a syphilitic etiology.

X-ray examination of the chest brought out many features. The predominant left ventricular enlargement was consistent with free aortic regurgitation. The normal aorta gave no support to the diagnosis of syphilitic heart disease, but did not rule it out. The dilated hilar vessels and the left auricular enlargement were consistent with functional mitral regurgitation, and the "slight" enlargement of the auricle, was not enough to presuppose the presence of mitral stenosis. All this evidence is in keeping with isolated aortic regurgitation due to either cause.

The laboratory data showed four positive Hinton reactions, which were good evidence of syphilitic infection. The two negative and the two unsatisfactory Wassermann reactions were in no sense against the diagnosis of syphilis, since the Hinton is the more sensitive of the two tests.

In summary, then, a fifty-three-year-old man with positive serologic tests and free aortic regurgitation developed rapidly progressive, predominantly left-sided, cardiac failure, a picture more consistent with syphilitic than with rheumatic disease of the aortic valve.

The picture of congestive heart failure, both of the left and of the right side of the heart, was quite clear. The onset was rather sudden, with increasing exertional dyspnea, ankle edema, cough and paroxysmal nocturnal dyspnea. Examination revealed pitting edema, cardiac enlargement, gallop rhythm,

poor heart sounds, orthopnea, rales in the lungs, and engorged neck veins. The negative urine and normal nonprotein nitrogen suggest that the amount of congestion in the kidneys was slight if any.

On cardiac therapy he did well at first, losing fluid satisfactorily. Apparently the paroxysmal dyspnea also improved, for we are told that it reappeared toward the end of his hospital stay, when he died in uncontrollable pulmonary edema. We do not know whether there was any reappearance of the right-sided cardiac failure.

In addition to these findings, however, there were others less easily explained on the basis of cardiac failure. The liver was large, but we are not told whether it was tender or whether it subsequently decreased in size with diuresis. With hepatic enlargement due to congestion of such sudden onset and short duration, one would expect that the liver would have been quite tender and painful. Palpable splenic enlargement, two fingerbreadths below the costal margin, is unusual with failure of such short duration, being usually seen in long-standing cases of chronic passive congestion, often with cardiac cirrhosis of the liver.

There remain other findings that cannot be explained on the basis of heart failure. The continuous fever was apparently the most striking feature of this patient's illness. It started three or four weeks before the onset of the failure and persisted even after the cardiac failure had improved. The elevated sedimentation rate was probably an accompaniment of the fever. The clubbed fingers could fit in with several of the disease pictures to be mentioned below, or they could represent a congenital and an entirely unrelated phenomenon. There was a moderate hypochromic anemia, which is also unexplained.

As the first possibility to explain these findings, one thinks of pulmonary disease. The patient's illness before the onset of cardiac decompensation involved the lungs. It started with cough and was followed by pleuritic pain, first on one side and then on the other. A film at that time is said to have shown "pleurisy on the left," but the meaning of this is not clear. Subsequently the patient developed fever, and although he had no symptoms, he was put to bed and was said to have had "double pneumonia." Following closely on this period of bed rest, he developed the picture of cardiac failure. Apparently the cough that marked the onset of the whole illness subsided, only to reappear with the onset of failure and to persist for an indefinite time.

One thinks of bilateral pulmonary infarctions with emboli arising from silent peripheral phlebotrombosis, although there is no story of hemoptysis. Low-grade pulmonary infection may arise on the basis of previous infarction. Against this idea, however, as against any attempt to explain the fever on the basis of pulmonary disease, is the demonstration of normal lungs by x-ray. Except for

the hilar congestion and minimal fluid in the costophrenic angles, there was no evidence of parenchymal disease. This finding is strong evidence against pulmonary infection, bacterial or otherwise, against pulmonary malignancy and against pulmonary infarction, at least at the time the film was taken.

It is difficult to explain the nature of the pulmonary episode at the outset. It appears to have been a low-grade, rapidly subsiding pulmonary infection.

Other possibilities considered by those in charge of the patient included subacute bacterial endocarditis. Consistent with this diagnosis are the fever, the clubbed fingers, the anemia, the enlarged spleen, and the normal white count in a patient with known cardiac disease. Against it, however, are the thirteen negative blood cultures, the absence of any clear-cut embolic phenomena, and the rarity of this complication with syphilitic heart disease, which we assume this patient had.

Although the picture was not that of active rheumatic fever in an adult, this disease was considered, and salicylates were tried. There was no response. It is interesting to note that the casts and the red cells that appeared in the urine at that time may well have been due to the effect of the massive doses of aspirin on the kidneys.

Finally the patient was given sulfadiazine, presumably on the chance that he might have had some bacterial infection susceptible to this drug. Again there was no response.

We are forced then to look elsewhere for the cause of the fever, and returning to those findings probably unexplained by the congestive failure, we have enlargement of the liver and of the spleen. Together these suggest hepatic cirrhosis, and in a known syphilitic patient one thinks of syphilitic involvement of the liver. This disease is usually asymptomatic and is sometimes accompanied by fever, as is cirrhosis of other types. Cirrhosis can give rise to clubbed fingers, and the anemia, although not of the usual macrocytic type, is not inconsistent.

Finally, a malignant neoplasm must be considered in any unexplained febrile illness in a person of this age. No primary site was apparent, but metastatic cancer of the liver is possible, although this would not explain the splenomegaly. Possibly the splenomegaly was entirely unrelated, having been the sequela of some such disease as malaria in earlier life.

One would like to be able to explain the whole picture by one disease process, and this can be done by supposing that this patient with syphilitic heart disease also had syphilitic disease of the liver.

CLINICAL DIAGNOSES

Acute rheumatic fever.

Rheumatic heart disease, with aortic regurgitation.

Congestive heart failure.

DR. LINENTHAL'S DIAGNOSES

Syphilitic heart disease, with aortic regurgitation.
Congestive heart failure.

Cirrhosis of liver (? syphilitic).

ANATOMICAL DIAGNOSES

Endocarditis, subacute bacterial, of aortic valve (pneumococcus Type 13).

Congenital bicuspid aortic valve.

Cardiac hypertrophy.

Embolic nephritis.

Splenomegaly.

Peripheral edema.

Pulmonary edema and congestion.

Bronchopneumonia.

Central congestion and necrosis of liver.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The clinician in charge of this patient tried to establish a diagnosis of bacterial endocarditis and, like Dr. Linenthal, finally voted against it. The autopsy, however, shows a subacute bacterial endocarditis involving the aortic valve. The valve had been previously damaged, but by neither a rheumatic nor a syphilitic process. The valve was a congenital bicuspid and on each cusp were attached friable vegetations 6 to 8 mm. in diameter. Some of these were nodular and contained foci of calcification. There was a perforation 8 mm. in diameter through the non-coronary cusp, which accounts for the regurgitation. We were able to recover Type 13 pneumococci from the heart's blood and the vegetations. The mitral valve was negative. The heart was moderately hypertrophied, weighing 500 gm.

As evidence of heart failure, we found peripheral edema, pulmonary edema and congestion, and central congestion and necrosis of the liver. The spleen was enlarged, weighing 500 gm. There was also terminal pneumonia in the left upper lobe.

RED CROSS BLOOD-DONOR SERVICE

A CERTAIN degree of confusion has continued to exist regarding the exact role of the Red Cross blood-donor centers, their functions and obligations and their relation to civilian defense, hospital blood banks and the private citizen. Many of the last, indeed, even including Red Cross workers, entertain the belief that the blood-donor center is a sort of civic pool to be drawn on in case of emergency, as one might take a book from a public library, were one bookishly inclined.

In view of the enormous quota of blood that the Red Cross has committed itself to obtain for this year of warfare, — a quota that, as previously in-

dicated,* is not yet being met, — a statement has been issued by Mr. Joseph R. Hamlen, chairman of the Boston Metropolitan Chapter, to remedy the confusion and ensure the continuance of good public relations.

The most important point to be made clear is that the American Red Cross is collecting blood exclusively for the armed forces at the request of the United States Army and Navy. As Mr. Hamlen states:

The blood at no time belongs to the Red Cross, but rather, from the moment it leaves the donor's veins, it is the property of the United States Army and Navy. The Red Cross is specifically forbidden from diverting the blood, except under direct orders of the Army and Navy. Under certain rare circumstances, such as the Coconut Grove disaster or enemy bombing, this blood can be released, but only with the consent of the Army and Navy.

The Red Cross is further under obligations not to furnish the names of donors to persons seeking donors for private patients, not to conduct any sort of a campaign to enlist donors for private patients, and to accept no blood other than that taken at its own blood-donor centers or by mobile units of those centers. Moreover, by an agreement between the American Red Cross and the Office of Civilian Defense, all hospitals whose blood banks are financed by OCD funds must refrain from public appeals for donors through the newspapers, radio or other accepted mediums of publicity within seventy-five miles of a Red Cross blood-donor center. The Red Cross Blood-Donor Service thus receives the priority it must have to attain its quotas — a service of paramount importance to a nation at war.

The private citizen may still be supplied with blood to the utmost limit of his needs, but it must be obtained at hospitals with blood banks, or from private or professional blood donors. For Army and Navy needs, which constitute the number one priority today, the Red Cross must have a clear track and the co-operation of every patriotic citizen.

EPIDEMIC JAUNDICE

Two types of cases of jaundice have been encountered during the present war, both of which may be said to have occurred in epidemic form. Catarrhal jaundice, or what the British like to call

*Editorial. Share the blood, *New Eng. J. Med.* 230 121, 1944.

"infective hepatitis," has probably occurred among the armed forces in this country, but its incidence has not been excessive and no serious or extensive epidemics of this disease have been reported. This disease, however, has occurred in epidemic form among civilians in England,^{1, 2} among the British armies in the Middle East³⁻⁵ and among German troops in occupied territories,⁶⁻⁸ and it is probably quite widespread in other localities. The second form of jaundice, which has occurred both in the American and British armed forces and in Brazil has come to be known as "homologous serum jaundice"⁹ and has already been commented on in these columns.¹⁰ The most widespread occurrence of this form of jaundice has been after vaccination against yellow fever. All the vaccines responsible for this type of jaundice have contained attenuated yellow-fever virus and human serum. Vaccines using the same strain of virus but omitting the human serum have now been used for more than a year, and so far as is known, no cases of jaundice have resulted.

The clinical features of the two types of jaundice are sufficiently similar so that it is difficult to tell them apart. Most cases of post-vaccination jaundice, however, have had a severer course, and fatalities have been commoner in this form. Deaths from either type of jaundice have been associated with widespread liver damage — that is, they have been due to acute or subacute yellow atrophy.

The chief distinction between the two forms of jaundice has been on epidemiologic grounds. The incubation period of catarrhal jaundice, according to data available in cases occurring after single or short exposures, is about four weeks but ranges from twenty to forty days. Patients with the disease are infectious during the preicteric stage and for a few days after the jaundice appears. Although no virus has been isolated from cases of catarrhal jaundice, the disease is believed to be transmitted from patient to patient by droplet infection, and suggestive results of experimental nasopharyngeal transmission have been reported.¹¹

Homologous serum jaundice, as implied in the term, has occurred only after the inoculation of convalescent serums or of vaccines containing human serum. The incubation period is two to four months, shorter incubation periods being quite rare.

Infections acquired from simple exposure to cases of post-immunization jaundice are extremely unusual. When they do occur, however, they are helpful in understanding the nature of this disease. In such cases, which occurred in uninoculated persons following contact with patients who develop jaundice after receiving measles convalescent serum have been reported.¹²

Several explanations for homologous serum jaundice may be mentioned. Is the jaundice following yellow-fever immunization a mild form of yellow fever in which the attenuated virus has retained viscerotropic properties? This seems unlikely because of the fact that no jaundice occurs with the same virus when human serum is not incorporated in the vaccine. Furthermore, this fails to explain the cases occurring after convalescent serums given for other diseases and which have similar clinical features, as well as a long incubation period. A second possibility is that the infected serum contains a virus that is capable of producing hepatitis in the homologous species. In this connection the virus may be the same as that of catarrhal jaundice but modified by the treatment to which it has been subjected in the preparation of the vaccine or of serum. Furthermore, the type of bodily reaction may be changed because of the fact that the infection is acquired after subcutaneous inoculation rather than by the nasopharyngeal route, which is the natural one for catarrhal jaundice. This might account for the long incubation period of homologous serum jaundice. Another possible explanation for this form of jaundice depends on the supposition that some toxic agent is introduced in the process of preparing the immunizing material. Finally, one might suppose that the homologous serum has been altered in the process of preparation in such a way that it becomes antigenic and capable of producing antibodies that react specifically with newly manufactured proteins in the liver, thus causing an inflammatory antigen-antibody reaction. The two explanations are difficult to rule out or to prove.

Some recent experiments in transmission support the view that the virus is identical with that of catarrhal jaundice or similar to it. Findlay and Martin¹³ obtained nasal washings from three patients in the preicteric or early icteric stage of jaundice.

the following yellow-fever vaccination and included these washings into the nares of three healthy unteers. The latter came down with jaundice in incubation periods of twenty-eight, thirty, and thirty days. There was considerable variation in the severity of the illnesses of these recipients, but the symptoms were similar to those of infective hepatitis.

A second series of experiments designed to determine the properties of any virus agent that might be responsible for the jaundice following yellow-fever immunization were carried out by workers at the National Institute of Health.¹⁴ They produced jaundice in human beings by the inoculation of two different lots of yellow-fever vaccine containing filtered human serum. They also produced jaundice by inoculating small amounts of filtered serum from either an individual or a group who had previously received yellow-fever vaccine containing human serum and who subsequently developed jaundice. They concluded that the jaundice-producing agent is filterable and survives drying in a vacuum, storing for long periods in serum at 4°C. and heating at 56°C. for half an hour in the dried state. They also obtained evidence that this agent is present in the blood before the jaundice appears but not two and a half months after the disappearance of the jaundice. Their experiments indicated that the agent is destroyed by ultraviolet radiation.

These two groups of experiments support the view that the cause of homologous serum jaundice is a virus similar to, if not identical with, that of ordinary catarrhal jaundice. If this view is correct, the prevention of such jaundice depends on exercising further care in the selection of donors for human serum or plasma: one must avoid those who have had or may have had catarrhal jaundice within two or three months of the time when they are bled.

A recent editorial calls attention to a possible source of epidemics of catarrhal jaundice.¹⁵ This is based on a report by Hallgren of an explosive institutional outbreak in which the infective agent was probably carried by water, inasmuch as a leak in the main sewer system might well have accounted for the pollution. Such a finding appears to be significant in the prevention and control of epidemic infectious hepatitis.

MEDICAL EPONYM

WATERHOUSE-FRIDERICHSEN SYNDROME

Rupert Waterhouse (b. 1873), pathologist and assistant physician at the Royal United Hospital, Bath, reported "A Case of Suprarenal Apoplexy" in the *Lancet* (1:577, 1911). A portion of the article follows:

A male child, aged 8 months . . . throughout the morning had been very drowsy and had "looked strange" . . . had not seemed in pain, had taken nourishment readily, and . . . the bowels had acted as usual. About 3 o'clock in the afternoon he vomited. . . . Previously the child had always seemed perfectly healthy. . . . On account of the parents' conscientious objection the child had never been vaccinated. . . .

On admission the infant was obviously very ill: complexion grey, eyes dull, breathing rapid, shallow, and noiseless; temperature 100.4°F., pulse 140, and respirations 72. Rales could be heard all over the chest. . . . There were no signs of meningitis, and nothing abnormal was to be seen in the mouth or fauces. Two hours after admission an extensive eruption of purple spots and blotches appeared over the whole trunk, upper arms and thighs. . . . The child rapidly grew worse. . . . and death occurred at 7:30 p.m.

. . . . The post-mortem examination was made 22 hours later. . . .

The lungs were congested and oedematous. . . . The suprarenal capsules were striking objects even before their removal from the body; of little more than normal size for a child of this age, they were both of a deep purple colour and evidently the seat of haemorrhage. . . . Microscopically the structure of the medulla was seen to be completely destroyed and replaced by effused blood. . . . All the other organs appeared natural. . . .

The case related above appears to form one of a distinct group . . . all infants between the ages of 2 and 15 months, and all of whom died after an illness lasting in the majority less than 24, and in none more than about 48 hours. In all but three a haemorrhagic rash of greater or less extent was present. . . . Apart from the lesions of the adrenals and the haemorrhagic rash, the most constant post-mortem findings have been intense engorgement of the lungs. . . .

Eight years later Carl Friderichsen (b. 1886), then assistant in the children's department of the

DEATHS

DORE — The Rev. Francis J. Dore, for the past nineteen years head of the biology department at Boston College, died February 28. He was in his sixty-eighth year.

Fr. Dore was graduated from Boston College in 1898, and from the Harvard Medical School in 1902. He practiced medicine in Boston until he entered the Society of Jesus in 1907. He was regent of the school of pharmacy at Fordham University from 1918 to 1922, and in 1925 came to Boston College from St. Andrews-on-the-Hudson, Poughkeepsie, New York. He was an honorary fellow of the Massachusetts Medical Society.

Two brothers and two sisters survive.

POTE — Leonard H. Pote, M.D., of Somerville, died December 3, 1943. He was in his seventieth year.

Dr. Pote received his degree from Harvard Medical School in 1900. He was a member of the Massachusetts Medical Society and the American Medical Association.

CORRESPONDENCE

CONFUSION OF NAMES

To the Editor: Since the similarity of my name and office address with those of another who is licensed to practice medicine in Massachusetts has, in the past, caused much confusion, I respectfully request that physicians who see fit to refer patients to me give my full name and exact office address.

184 Bay State Road
Boston

JOSEPH RESNIK, M.D.

AGE LIMIT RAISED FOR RESTRICTED SHORE DUTY IN MEDICAL CORPS OF THE NAVY

To the Editor: On March 1, owing to the continuing urgent need for physicians in the Navy, the maximum age limit for specialist medical officers was raised from the age of fifty to fifty-five. This office will therefore be glad to accept applications from physicians who have not reached their fifty-fifth birthday.

The following is quoted from the telegram of authorization:

Authority is hereby granted to forward applications for appointment in class MC-V(S) of individuals whose physical qualifications justify their appointment for limited shore duty only. If approved it is intended to appoint these officers to duty in naval dispensaries, navy yards, naval training stations, and to the Navy and Marine Corps recruiting service, thus making available for sea and foreign assignments physically and otherwise qualified medical officers now detailed to this type of duty.

COMMANDER JOHN P. MONKS, MC-V(S) U.S.N.R.
Senior Medical Officer

Office of Naval Officer Procurement
150 Causeway Street
Boston

NOTICES

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis

Association, 554 Columbus Avenue, Boston, on Tuesday, March 21, at twelve noon. Dr. Chester S. Keefer will on the topic "Penicillin."

Physicians are cordially invited to attend.

TUFTS MEDICAL ALUMNI ASSOCIATION

The annual meeting and dinner of the Tufts Medical Alumni Association will be held on March 29 at the Plaza Hotel, Boston. The committee on arrangements consists of Dr. William E. Browne, chairman, Dr. Harry Blum, secretary-treasurer, and Drs. Carl Barse, Roy J. Heff, James W. Manary and Frank R. Ober.

The guest speaker will be Dr. Morris Fishbein, editor of the *Journal of the American Medical Association*, who will on the subject "Probable Changes in the Practice of Medicine, Harmful to the Patient, If Bills Now Pending in Washington Become Law." Dr. Leonard Carmichael, president of Tufts College, will speak on the topic "First Fifty Years as a Prelude to Greater Things." Other speakers will include Dr. A. K. Paine, president of the American Medical Association, Captain A. Warren Stearns (MC), U.S.N.R., on leave, and Dr. Carl T. Phillips, of Putnam, Connecticut.

NEW ENGLAND PATHOLOGICAL SOCIETY

The next meeting of the New England Pathological Society will be held in the amphitheater of the Children's Hospital, Boston, on Thursday, March 16, at 8 p.m.

PROGRAM

Peripheral Thrombosis and Gangrene of the Extremities in Early Life. Dr. Robert E. Gross.

Neurofibroma with Special Reference to Skeletal Involvement. Dr. William T. Green.

Tumors of the Brain and Spinal Cord in Infancy and Childhood. Dr. Franc D. Ingraham.

Some Peculiarities of Malignant Tumors in Early Life. Dr. Sidney Farber.

Physicians and medical students are cordially invited to attend.

NEW ENGLAND OPHTHALMOLOGICAL SOCIETY

The 358th meeting of the New England Ophthalmological Society will be held at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, on Tuesday, March 16, at 8 p.m.

Following the business meeting, Dr. David G. Coggeshall will speak on the topic "Some Disturbances of Eye Movement in Cerebellar Disease." Dr. Joseph Igersheimer will speak on the subject "Intraocular Pressure and Its Relation to Retinal Extravasation."

ALLERTON HOSPITAL

The regular monthly meeting of the Medical Staff of Allerton Hospital will be held at the Nurses' Home, 300 North Street, Brookline, on Thursday, March 16, at 8 p.m. Luncheon will be served.

SOCIETY MEETINGS AND CONFERENCES CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MARCH 16

THURSDAY, MARCH 16
*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thannhauser. J. Pratt Diagnostic Hospital.
*1:00 p.m. Minimal Water Requirements of Castaways. I. Gamble. Amphitheater, Children's Hospital, Boston.
*8:00 p.m. New England Pathological Society. Amphitheater, Children's Hospital, Boston.

FRIDAY, MARCH 17
*9:00-10:00 a.m. Brain Electricity: Observations on the cephalogram. Lieutenant Commander Herbert J. Har- V(S), U.S.N.R. Joseph H. Pratt Diagnostic Hospital

Number 11

THE NUTRITIONAL SITUATION IN THE CAMPS OF THE UNOCCUPIED ZONE OF FRANCE IN 1941 AND 1942 AND ITS CONSEQUENCES*

RENÉ ZIMMER, JOSEPH WEILL AND MAURICE DUBOIS

NIMES, FRANCE

EARLY in 1942 the Commission on Hygiene called attention to a grave danger threatening the very existence of the internment camps. Malnutrition, or the so-called "disease of starvation," had invaded them. Although its initial attack in the spring of 1941 was halted by the coming of summer, a new wave swept over the camps with the first arrival of cold weather. The disease spread rapidly, like a contagion, revealing profound physical exhaustion and extreme misery. The symptoms, slight at first, then more and more marked, became increasingly serious and showed in many respects the classic picture observed during famines, whereas other, much less well-known symptoms seemed peculiar to this particular outbreak of malnutrition. The number of deaths increased. During the first period, from September, 1941, to January, 1942, there was a daily average of 2 deaths in each camp, and in certain camps 5 every two days. Four weeks after a group of 40 patients had been transferred to a camp hospital, they were all dead.

This disease resembled an epidemic, spreading to all the barracks, penetrating into all the divisions, striking all the camps, and threatening a population of more than 10,000 men, women and adolescents. The men were affected first and seemed to be much less resistant than were the women and the young people, but later the character of this collective disease underwent profound changes.

The commission sounded the alarm at the meeting of January 14, 1942. It proposed urgent measures of assistance, and at the same time submitted them to the approval of the inspector general of the camps. The plans included the following essential features: the assignment by the commission of

physician-investigators to the camps, their mission being to examine all the internees from the point of view of nutrition and to organize and co-ordinate a program of assistance by all the relief agencies in collaboration with the sanitary services of the camps; hospital care for those suffering from the disease of starvation, in barracks especially fitted out to facilitate their observation and treatment; organization of special dietary kitchens under the common responsibility of the relief agencies; provision of urgent medical treatment where it was needed, together with the administration on a large scale of dietary products, vitamins, minerals and general stimulants; and isolation of those in danger of developing serious starvation symptoms in prophylactic centers separate from the camps proper.

Today we report the first results of this program of assistance and observation. First of all we wish to express our thanks to the inspector general of the camps, by whose swift and energetic administrative measures the organization of assistance was made almost immediately possible.

The medical investigators began their work in most of the centers in February, 1942. Kitchens were organized for the cachectic (starving) patients in the most important camps. A close collaboration was established between the medical investigators and the sanitary services of the camps. Nine thousand persons have been thoroughly examined and regularly followed up.

The plan of the physicians assigned by the Commission on Hygiene included an investigation in the huts of patients affected by the syndrome of starvation, a clinical and therapeutic study of the cachectic patients under hospital care in the barracks, a study of the nutritional situation, the co-ordination of the different relief agencies in the camps and the elaboration of medical principles guiding their work and a critical study of the results obtained.

PRELIMINARY DATA

The investigation took the form of a methodical medical examination of all the inhabitants, section

*This report was originally presented on July 1, 1942, by the Commission on Hygiene of the Co-ordinating Committee for Relief in the Camps at Nimes, France. The commission consisted of the representatives of the organizations that were particularly interested in the problem, namely: the Unitarian Service Committee, the Swiss Red Cross, and the Jewish (and the purpose of the attempts then being made to solve the medical and hygienic problems arising in the supervised concentration camps in France, to collaborate for the sanitary protection of the internees and to establish contact with the international organizations interested in these problems. The report was translated and shortened under the auspices of the Unitarian Service Committee.

by section and barrack by barrack. Of all the internees of the camps 85 to 95 per cent were thus examined. At a preliminary session they were weighed and measured, undressed. Their medical histories were noted, their pulse rates and arterial blood pressures were recorded, and whenever possible their weights before internment were ascertained. At a later session the patients were medically examined, undressed, and the findings were entered on individual record cards. The investi-

gation had to be restricted to simple and rapid examinations, as is necessary in the study of large groups. The following criteria were used for the primary classification of the patients: height and weight, condition of the skin and the adjacent subcutaneous tissues, muscular tonus, posture, condition of the cardiovascular system, the presence and location of edema and the blood picture. Such criteria were sufficient to permit classification of the patient with regard to the urgency for and importance of the treatment required by their condition.

Criteria

Measurements of height and weight. A weight-height index of all the examined persons was set up, making it possible to judge at a glance the weight conditions of the internees. The index has a practical value only if it is calculated in relation to the physiologic coefficient of weight to height, deter-

mined according to the corrected tables of Dubois-Reymond. The results of such measurements on the men and women of an entire camp are presented in Figures 1 and 2, plotted as frequency of occurrence against percentage of physiologic weight and against a weight-height index. It was necessary to take into consideration, in weighing and measuring, the errors in weight caused by the edemas and those in height caused by the frequent scolioses due to the osteopathy of starvation. It was therefore important

to register whenever possible the preinternment weight and height as entered on the military identification papers of the men. Although a considerable loss of weight in a given subject is a factor of definite prognostic value nevertheless experience has shown that it does not allow one to pronounce his condition as irreversible. Regular weighing has more significance if it is done simultaneously for a whole camp and if the results among the cachectic patients are compared with the weight of noncachectic persons in the same camp. It has been observed that considerably emaciated patients almost always develop hernia and that this symptom is hardly ever absent even in young men who are precachectic subjects.

Examination of skin and subcutaneous tissues. From the threatened to the cachectic stage, the atrophy progresses through all degrees, arriving finally at a stage of veritable "anatomical dissection." The degree of atrophy may best be estimated by examin-

FIGURE 1. Percentage Distribution of Male Inmates of Huts A, D, E, F, G and H. According to a Weight-Height Index (Camp Gurs: June, 1942).

ing the patient posteriorly. In the final stage, particularly in the case of formerly obese persons, the skin hangs on the body like a garment that has become too large.

Muscular tonus. The signs of muscular hypotony could be observed quite early in a large number of cases. This explains to a certain degree the difficulty that many patients had in standing up. In several photographs it was noticed that the subject was unable to keep his head motionless. The posture of the patients was defective. Scoliosis occurred with increasing frequency. At a certain stage the patients dropped the things they held in their hands. They became unable to make the slightest muscular effort. Measurements made with the dynamometer

signal of the state of starvation. It was accompanied by the classic sign of empty peripheral veins.

Circulatory apparatus. Systematic registration of the pulse — rate, quality and rhythm — is important partly on account of the ease by which these measurements can be taken and partly for the valuable information that they furnish. Sometimes acceleration of the pulse, or tachycardia, was observed, sometimes a slowing, or bradycardia. At a certain stage there was sometimes irregularity of the pulse rate. The arterial blood pressure was measured in all the patients.

Edema. The edema was most significant if it was fixed, large and visceral. A characteristic physiognomy of the undernourished caused by a combina-

FIGURE 2. Percentage Distribution of Female Inmates of Huts I, J, K, and L. According to a Weight-Height Index (Camp Gursi, June, 1942).

showed that in a number of patients the figures obtained were smaller than those that would correspond to the strength of a small boy of ten or twelve.

Position. In the advanced stage the patients were unable to stand up, and were obliged to creep on all fours to get back to their beds. It was often of interest to measure the length of time during which the patients were able to stand. After a few seconds or minutes on their feet they complained of pricking pain in the limbs and of trembling, sometimes accompanied by profuse sweating. Fainting was frequent when attempts were made to maintain a standing position and often constituted the alarm

tion of swellings due to edema and anemia was the sign of decided physiologic disturbance.

Blood examination. Examination of blood taken at random from the undernourished showed in every case the presence of anemia.

Classification of Patients

As in the presence of a large epidemic of disease, it was important to isolate from the beginning those who were seriously affected, and furthermore to discover the first symptoms of malnutrition in others in order to limit the damage by energetic prophylactic measures. The fact that the patients exhibiting the syndrome of malnutrition were concentrated

in one place and subject to a uniform, easily controlled discipline made possible an extensive scientific analysis of the symptoms observed as well as observation of the development of the application and the study of an appropriate diet. This study may enable us to oppose effectively this syndrome, which is beginning to make its appearance among the general French population.

After examination each internee was classified under one of the following categories: cachectic, precachectic, threatened and normal.

The cachectics were immediately recognized from a distance by their extreme emaciation and their characteristic physiognomy. Their skeletonlike thin-

patients (3.7 per cent), 839 precachectic patients (9.3 per cent) and 4000 threatened persons (42.6 per cent), the remainder (42.6 per cent) appeared not being in need of immediate medical attention.

Malnutrition, which imitates some of the characteristics of a virulent epidemic of communicable disease, had not yet reached its peak in the camp. Systematic investigation revealed each week precachectic patients and those threatened with this condition.

CLINICAL AND THERAPEUTIC STUDY

According to the results of the preliminary investigation, it appeared that half the actual population

FIGURE 3. Incidence of Edema of Starvation among Men and Women, Expressed as Percentage of Total Inmates (Camp Gurs: June, 1942).

ness was impressive; muscular and skin atrophy was general. The subcutaneous layer of fat had disappeared a long time previously. The skin was dry and scaly. Many adults of average height were no more than 40 kilograms in weight. The complexion of these patients was either ash gray or of a subicteric pallor, depending on the predominance either of a shade of cyanosis or of a hemolytic process, but the pallor of the mucous membranes and the anemia were features of almost all cases. Combined with their emaciated features the patients presented a corpselike appearance. The detailed clinical description of this type of patient is given below.

The precachectic patients showed the same symptoms to a lesser degree. Both muscular atrophy and anemia were less pronounced. The loss of weight was not so far advanced and the general state was less serious. The application of different tests showed that they had been affected less seriously.

The threatened patients had on the whole maintained a better general state of health than had those in the previous two categories. Here the tendency toward the edemas of starvation had begun to appear, but they were transitory, shifting and recurrent. Emaciation was, however, quite common. In this group were included the convalescents from typhoid fever and patients with acute gastric and duodenal ulcers, advanced tuberculosis and Parkinson's disease, as well as those with chronic decompensated heart disease.

In a population of 11,000 internees, of whom 9000 were examined,* there were found 331 cachectic

*It is not clear from the text of the report whether the 2000 subjects not examined were considered normal and free from medical need or whether the 3830 subjects not included among the three categories in the 9000 examined were normal. — TRANSLATOR.

of the camps was threatened by the form of symptoms of the disease of starvation, which appeared in various clinical forms.

Clinical Forms of Starvation

Wet form. Approximately 50 per cent of the internees who were examined showed the edema of malnutrition. It was found especially among Spaniards and Italians. Edema was not, however, the sole or pathognomonic symptom of this functional disturbance.

Contrary to the usually accepted ideas of our initial observations, we found a higher proportion of edemas of starvation among women than among men. Still, a greater number of men showed bradycardia and lowered blood pressure, which proves that they had been more seriously affected. Also it was especially among men that ascites occurred with relative frequency (Fig. 3). In accordance with what has often been stated, we found that edema affected young girls between the ages of seventeen and twenty-two who had fairly regular menses.

These edemas were located similarly in a considerable proportion of the patients, in the following parts of the body as follows: the top of the feet, the malleolus on the inner side of the ankles, the lower part of the face, under the chin, that over the cheekbone, and the eyelids.

The soft, white edema, at first transitory and shifting, became gradually fixed after several weeks. This was observed especially in the lower extremities. A certain number of cases of edema were observed in which the patients were un-

of its existence or were not uncomfortable because of its presence. Ascites formed about 10 per cent of the edemas, and was more resistant to treatment with diuretics and additional feeding than was peripheral or subcutaneous edema.

Sometimes edema was observed in men showing a generally satisfactory state of health with no emaciation or other symptoms of malnutrition, with well-developed muscles, and with the subcutaneous layer of fat preserved. Almost all these men belonged to the canteen or kitchen staffs. This edema was caused by unbalanced diet or was of toxic alimentary origin.*

Certain associated symptoms occurred in all clinical forms of starvation. In addition to edema, the patients suffered from frequent urination, especially at night. This symptom was related either to the general demineralization or to the cold, because the nights were cool and the barracks drafty.† Pleural effusion, another form of visceral edema, was of more frequent appearance. It differed neither in development nor in prognosis from other forms of edema.

On the whole, the patients with edema maintained good appetites until a very advanced stage of their illness. The extreme fatigability from which they all suffered led, at a certain stage of the disease, to a persistent painful sensation. Sometimes the pain appeared only after a slight effort. Then the typical physiognomy of the starving cachectic patient appeared — the anemic and puffy features — and marked emaciation. Infection of the skin was frequent, and great sensitiveness to cold developed. The body temperature was often low, sometimes below 35°C. (95°F.).

Examination of blood taken at random from cachectic patients and those threatened with this condition showed that all were anemic. In none of the specimens examined did the red-cell count reach 4,000,000. In the great majority it was approximately 3,000,000. In hardly 5 per cent of all cases was the hemoglobin above 70 per cent. In all other cases it ranged about 60 per cent.

As regards both blood values and weight, the danger point was found to be a diminution of 30 per cent from the physiologic norm.

Urinalysis did not show pathologic features.

Dry form. The dry form was characterized by the absence of edema. It was found especially among the Spaniards and Italians — a reason for its predominance, for example, in the camp at Rivesaltes. It should be mentioned that these men had been suffering from chronic undernourishment for many years, and their ancestors for centuries. Their skin was dry, atrophied and often scaly, and the atrophy in these cases took particularly severe forms.

*Or possibly from vascular stasis related to long hours on their feet — TRANSLATOR.

†Perhaps the bladder wall lacked tone or there was infection of the urinary tract. — TRANSLATOR.

Anemic form. Examinations of the blood smears now under way show a certain number of hyperchromic anemias — 43 per cent of the cases studied. This finding, combined with the results of neurologic examinations, is of great pathological and therapeutic importance. It would be worth determining whether the lack of the extrinsic principle, present especially in meat, is responsible for anemias of the pernicious type, combined sometimes with the neuroanemic syndrome. It is to be noted that the patient showing the most refractory neurologic symptoms, in spite of having gained in weight, was one whose blood analysis gave a color index of 1.23, with 57 per cent hemoglobin, 2,330,000 red corpuscles and 2700 leukocytes. The sedimentation rate of these patients was not as a rule accelerated.

Petechiae with segmental distribution were observed in some cases on the dorsum of the hands and forearms.

Vasolabile form. At the beginning of the illness the blood pressure and disturbances of the circulatory system were irregular. They showed deviations from the normal in both directions, sometimes between morning and evening, especially in the case of patients less severely affected. Later hypotension became constant; it was usually combined with bradycardia, which, transitory at first, also became permanent. At that point hypotension became an indication of the gravity of malnutrition. Hypertension, which was observed more frequently than is generally supposed, in spite of the general asthenia and loss of strength that occurred in severe cases, remained permanent up to the terminal stages.

The heart, like the other muscles, seemed to suffer from hydremia and atrophy. One was frequently surprised to find a double first sound without any other sign of tachycardia. Irregularities of rhythm — partial or complete arrhythmia — were not observed oftener than under other conditions.

Neurologic form. Ataxia and Romberg's sign were the most noticeable symptoms of the neurologic form. The reflexes were as a rule exaggerated. Polyneuritic pains and paresthesias were present. Examination of the ears was usually negative. General sensitivity was normal. The rate of blood sedimentation was generally much accelerated. Some patients showed a striking mixture of the Parkinsonian and ataxic syndromes. The muscles became spastic and the movements of the hands jerky, and the feet described random semicircles on walking. Once the patients had started on their way they had a fixed posture. They seemed to throw their whole body headlong, and stopped only with difficulty. Tests of muscular strength, as for example by the methods of Barré, showed weakness, just as did tests of muscular tonicity. The knee jerks were absent. The folds of the buttocks tended to be shallow.

Mental form. Patients with the mental form, whose gaze was dull and apathetic, were entirely disoriented. They answered questions in monosyllables and only after a certain delay. Weakened to an extreme degree, they collapsed on their straw mattresses. The states of mental confusion and of amnesia were impressive. Even when convalescence was advanced, the slowness of the mental processes was striking. Spasmodic laughing or crying was often observed. In some cases, in the ataxic phase preceding death, bulbar manifestations and symptoms of meningeal irritation were observed.

Lumbar puncture of the comatose patients disclosed nothing pathologic except a slight Claude's hypertension. Lumbar puncture was contraindicated, however, in such of these patients as were already in shock and suffering from circulatory abnormalities.

Conclusion. It is certain that a more protracted study will enable us better to differentiate the various forms we have mentioned and to add others. But these forms were experienced in every camp, with one form or the other predominating according to the geographic location of the camp or to the origin of the internees. The determination of these clinical categories is extremely important for the prognosis and treatment of the patients, as well as for the purpose of scientific research.

Development and Termination

Starvation led naturally to death, unless there was drastic intervention. Cold, hazardous hygienic conditions, restrictions of freedom of movement and lowered morale hastened the fatal outcome.

The meticulous observation of the different modes of death was highly instructive from the pathological point of view. One was impressed by the abrupt transition from an apparently normal state, when the patient attended to his business, to a coma that was followed by death after a more or less short interval. In other cases the patients were attacked more rapidly, in full career, as it were, and collapsed while walking or passed away in their sleep. In some other cases they expired slowly with all the signs of a progressive asthenia.

Death caused by pre-existent or contributory illnesses is not discussed here.

The chief physician of the camp at Vernet could find nothing worthy of note macroscopically in connection with the several autopsies that he had performed, except the existence of cerebral edema in some cases.

It is an interesting fact that the more experience one acquires, the less possible it becomes to predict, through persistent observation of a severe or even a hopeless case, the approximate date of death, or even to be sure of its occurrence.

During January and February, 1942, there were 43 and 49 deaths, respectively, in Camp I (about 400 internees), and 59 and 38 in Camp II (about

2800 internees). With a few exceptions the cause of death was essential malnutrition.

Complications

Tuberculosis. In one camp, well equipped for this purpose, 2000 x-ray examinations of the chest were made. Thirty cases of pulmonary tuberculosis were discovered. The affected persons were not aware of having the disease. Twenty of the cases were of the fibrosclerotic, nonprogressive type, but in 10 cases the lesions were progressive and in 3 of these there was disseminated tuberculosis.

Cardiac disease. Enlargement of the heart was found frequently among people in their fifties—20 per cent of the inhabitants. It was not ascertained whether the apparent enlargement was due to muscular hypertrophy or whether in some cases it was due to the presence of a pericardial exudate. The aorta was ordinarily transparent along its whole course. It is also worth mentioning that the bronchovascular shadow was particularly marked.

Disease of the bones. In general, marked decalcification of the ribs and of the vertebral column was noticeable; sometimes the bony trabeculae were visible. All these symptoms are typical of the state of malnutrition. They are the signs of an abnormally intense degree of general decalcification and demineralization.

Vascular disorders. Angiospasm of the extremities of the fingers and feet was frequently observed. Certain cases were so pronounced that they suggested a diagnosis of Raynaud's disease, but administration of vitamins, especially of pellagra preventive vitamin, brought about improvement. Freezing of the extremities, sometimes severe, occurred in a considerable number of persons in winter. There were many cases of arcus senilis, and precocious senility was frequent.

Endocrine disorders. Clinical and x-ray findings enable us to say a few words about disturbances of endocrine functions. Lack of equipment, however, has restricted investigations in this particular field.

Hyperthyroidism was rare, but there were a few cases. We plan to study this problem later when we can undertake more systematic research. There were many cases of goiter. The great proportion of pendant or pendulous goiters was astonishing. Thyroid disease was sometimes connected with amenorrhea frequently observed—in 30 per cent of the women. Puberty seemed in young girls to be retarded. In one of the large camps there were 171 cases of amenorrhea in women between the ages of fifteen and forty-five, including the following associated conditions: bradycardia, 21 cases (12 per cent); low blood pressure, 22 cases (13 per cent); high blood pressure, 3 cases (2 per cent); and edema, 87 cases, 47 of them slight (51 per cent).

Adrenal insufficiency was not studied, but the existence of hypotension, hypoglycemia and asthenia awakens interest in an investigation dealing with

these characteristic functional disturbances. The existence of spermatogenic troubles, commonly occurring among the debilitated, assumes more than a theoretical importance in the camps. The presence of genital endocrine troubles makes it probable that the hypophysis is also correspondingly affected. On the other hand, it is undeniable that the not uncommon diabetic internees benefit by the starvation diet. No diabetic coma was observed. The same statement applies to various diatheses.

Prognosis

The characteristic curve of an epidemic of communicable disease shows a progressive increase in morbidity in the first stage following the outbreak, and reaches a plateau as the force of the infection begins to exhaust itself or because of effective measures taken to fight the spread of the disease. In the third stage the number of new cases progressively diminishes.

The "disease of starvation," which imitates these characteristics of an epidemic of communicable disease, has not yet reached its peak in the camps. Systematic investigation reveals each week new pre-cachectic cases and persons newly threatened with this condition. The pathogenic factors are far from having exhausted their scope. It is possible, however, to review the elements that make a prognosis possible.

Sex. The records of the women are especially significant. Their attacks came after a delay of about ten months, and the increasing number of women actually affected by the syndrome of malnutrition illustrates eloquently the general aggravation of the situation. The fact that their caloric needs are 20 per cent less than those of men explains in part why women are better protected against starvation than are men. It seems that by now their resistance has been exhausted and that at present the prognosis for women is worse than formerly.

Seasons. There is a better chance to save a patient during the mild seasons of the year than during winter. Cold aggravates the prognosis because of the weakness and the increase in caloric requirements it causes. Edemas were observed to disappear under the sole influence of warm weather. It is certain that the persons who died in the past winter lost their lives as much because of cold as by reason of starvation. This effect of the cold on the undernourished is a frequent observation and causes among other symptoms an abnormally low body temperature. The occurrence of a large number of often severe frostbites, even at the end of winter, is connected with the damaging effect of cold on the circulation.

What has been said about the vasolabile type of starvation explains that these persons are also extremely sensitive to the effect of heat in summer, when the danger of dysentery also lies in wait for them. Thus, the two seasons with extremes of weather are full of danger for the undernourished.

Hypotension. Among the factors of prognosis is hypotension, which, once firmly established, is a more serious factor than is bradycardia.

Clinical types. Among the clinical types the neurological and mental types of malnutrition have the most unfavorable prognosis.

Intestinal complications. The prognosis is very bad when diarrhea makes its appearance, because of the dehydration, demineralization and defective assimilation of food and vitamins that follow in its wake. It is noticeable that its frequency varies greatly in the different camps.

Purpura. The appearance of purpura is an aggravating and alarming factor.

Asthenia. The impossibility of keeping a patient in the standing position for a few minutes calls for great caution in the handling of this disease. It is absolutely necessary to impose strict rest on these patients if one would avoid exposing them to the danger of an accidental death, which may occur after an untimely or unsupervised rising, often in response to orders.

Atrophy. Pronounced atrophy and intense emaciation are inseparable companions of cachexia, and they suggest an unfavorable prognosis.

Therapeutic intervention. The chances of recovery depend on the age of the patient, on the season of the year, on a certain number of factors enumerated above, on early treatment and above all on the intensity of the chosen treatment. In contrast to the general belief, there is no state, except the final coma, when the disease is irreversible. In spite of striking loss of weight, profound asthenia and a dangerous general condition of health, it was possible to save, through energetic and persistent therapeutical effort, patients who were considered beyond help. This knowledge has a valuable social significance and seriously modifies all our pathological and therapeutic conceptions.

Hypovitaminoses

The exact role of vitamin deprivation in malnutrition cannot be evaluated at present. Although the signs of insufficient caloric intake — loss of weight, emaciation and so forth — are obvious, clinical research is not yet advanced enough to establish with certainty a causal relation between a certain type of malnutrition and a corresponding hypovitaminosis. Moreover, the need for vitamins varies and depends on individual physiologic factors and endogenous influences that regulate the differences in the absorption and utilization of vitamins. At present we must limit ourselves to a review of the different manifestations of the early stage of starvation, without attempting to establish too definite causal connections among the different groups of facts.

Vitamin C. We have already mentioned some patients with a segmental distribution of petechiae on the back of the hands and forearms. Bloody suf-

fusions of the gums and unusually severe hemorrhages were also described by dentists. It was noticed that the vegetables served in the camps were especially poor in vitamins C and D. Therapy with vitamin C gave satisfactory results in these cases. It has not been possible up to the present to determine the elimination of vitamin C in the urine and to proceed to tests of saturation.

Vitamin D. There are many cases of rachitis among the children. The number of severe forms is not alarming, but there are many painful ones. The proportion of scolioses is large. Luckily most of these patients are not beyond recovery. Careful supervision and systematic and early treatment are indispensable. Caries of the teeth is widely prevalent, but the physicians are particularly struck by the cases of gingivitis and periostitis. In a number of cases the loss of fingernails was checked under the influence of a combined antirachitic, calcium and vitamin treatment.

Vitamin A. Recovery by the use of vitamin A was observed in a certain number of persistent eczemas and trophic ulcers occurring among young people. There were 2 cases of xerophthalmia. In certain cases, night blindness was observed. On account of lack of equipment only empirical methods were used; therefore a precise determination of the percentage of the affected cases was not possible. There were several cases of precocious presbyopia. Sometimes there were striking cases of pallor involving the whole pupil, — 10 per cent of the cases, — although the optic nerve was not diseased and there were no errors of refraction. In the opinion of all the physicians who have examined the internees, the lack of vitamin A is particularly noticeable.

Vitamin B. The good therapeutic results observed in the mental and neurologic cases, as well as in cases of neuroanemia after the administration of vitamin B₁ and brewer's yeast, indicate a lack of vitamin B₁ in these cases. The prevalence of meteorism in almost the entire population of internees is equally striking. Lack of vitamin B₁, hindering the assimilation of food, can be suspected of playing a decisive role in producing this symptom.

It would be interesting to know whether the numerous cases of diarrhea were caused partly by deficiency of pellagra-preventive vitamin. This possibility must be especially considered if a severe enteritis is accompanied by glossitis or aphthous stomatitis. These cases were more frequent than is ordinarily supposed. The sudden disappearance of all symptoms after two days' treatment with the amide of nicotinic acid proves that these disorders result from a vitamin deficiency.

STUDY OF THE NUTRITIONAL SITUATION

It is obvious that the state of functional distress found in the internees is brought about by quantitative and qualitative inadequacies in the food supply. Before starting on the study and interpretation

of the nutrient value of the food supplies in question, however, it seems advisable to give a review and a summary of the elementary facts regarding the caloric or energy principles of nutrition. It is sufficient to review briefly the indispensable elements of a normal ration and to compare it with the ration served to the internees in the camps.

The standard figures established by the Committee of the Health Section of the League of Nations in 1936 for a normal daily ration state that an adult of medium weight, at absolute rest, requires a daily ration of 2000 calories. The expenditure of energy of the same person leading an ordinary life without manual labor is 2400 calories. The additional expenditure of the muscles in case of light work amounts to 75 calories an hour, or about 600 calories a day, which gives the total of 3000 calories. When the energy value of the ration — that is, the caloric supply it furnishes — is lower than what is spent, the organism has to draw on its resources to make up the deficit by using up its own tissues.

Nutritional deficiency produces a more or less considerable emaciation, in the first place, according to the degree of insufficiency of the food supply. In order to provide for the unavoidable, minimal physiologic expenditure, the organism first uses up the most calorigenic substances, giving the greatest return combined with the least possible spending — that is, fats. This borrowing from the adipose tissue is not deleterious provided that it does not proceed beyond a certain limit and that the balance of the ration is kept above the minimum.

The menace of malnutrition begins when this supply of fat gives out. The proteins provided by the muscular and organic tissues are then called on to furnish the missing balance. From this point on the emaciation is more conspicuous, because the proteins furnish only 4 calories to the gram, — that is, only half the amount provided by 1 gm. of fatty substance. The attack on the protein reserve brings about the most disastrous consequences, because the organism is compelled to draw its supplementary caloric needs from the tissues of superior importance — the muscles and viscera. At this state, catastrophic emaciation is observed.

It is true that as a result of chronic undernourishment a certain state of adaptation is established in which the energy or caloric output is lower than normal. After a certain time undernourishment diminishes the volume of the body until a smaller amount of food becomes sufficient to supply the body, which has become reduced in size, through loss of protein from the organs and of fats from the adipose layers. But if the supply of calories drops even farther, physiologic adaptation becomes impossible.

Rations lower than 1800 calories a day for adults produce considerable emaciation and functional disturbances of various degrees of severity.

Besides containing a certain number of useful calories, different types of food have specific qualities that can in no way be supplied by other nutritive materials. To secure the normal well-being of the organism one must have a balanced ration containing minerals and vitamins as well as the indispensable minimal quantities of carbohydrates, fats and proteins. Nothing can replace these basic and indispensable elements if the living cell is to function properly.

For keeping up the energy balance of the food ration, the following proportions are customary in the countries of western civilization: 50 per cent carbohydrates, 30 per cent lipids and 15 per cent proteins. Sixty per cent of the protein should be of animal origin.

A one-sided diet causes profound physicochemical disturbances of the tissues and organs: the organism becomes incapable of maintaining the calcium of the body and the mineral balance is destroyed. This explains the bone diseases and edemas of starvation that develop with epidemic-like prevalence among those who are suffering from starvation.

Not all the proteins satisfy the needs of the organism with equal efficiency. No matter how large the supply may be, proteins of vegetable origin especially fail in this respect. Some specific needs can be supplied satisfactorily only by animal proteins on account of their higher content of essential amino acids.

Malnutrition is caused by chronic quantitative and qualitative insufficiency of the food supply. It seems necessary

to emphasize this obvious truth because of certain irresponsible opinions on the subject.

Quantitative Value of Food in Camps

The following is an example of the diet per person served to the internees in one of the camps during one month, from October 1 to 30, 1941.

	grams	calories
Bread	7500	17000
Fat	240	2160
Sugar	480	1960
Pumpkin*	30000	6100
Jam	2225	2250
Sardines	1800	1674
Cheese	200	600
Meat	913	911
Tripe	770	465
Carrots†	3750	1406
Cabbage†	3750	1125
		<hr/> 35651

*Served morning and evening for three consecutive weeks.

†Served morning and evening for one week.

This gave an average daily intake of 1188 calories, comprised as follows: protein of animal origin, 15 gm.; protein of vegetable origin, 37 gm.; fat of animal origin, 12 gm.; fat of vegetable origin, 2 gm.; and carbohydrates, 210 gm. When this record of calories was drawn up, the desiccation of the foods, which, according to competent authorities, causes a loss amounting to 15 to 20 per cent in weight, was not taken into consideration, nor was the fact that sardines, for example, contain 30 per cent of their weight as salt, nor was allowance made for the coefficient of resorption. Taking into account all these considerations, the value of the daily rations did not surpass 950 calories per person.

In another camp the quantitative value of the daily ration per person amounted to 1070 calories on February 26 and to 1092 calories on March 4. There was included in the calculation the additional food rationed out for the cachectic patients by the Commissary Department. This means that the caloric value of the actual average camp fare was about 100 calories less than the figure given. In a third camp the mean caloric value of the daily ration per person (determined by weighing) was 958 in June, 1942. In still another camp the accounts of the Commissary Department showed, on paper, daily rations of 1310 caloric value per person. But by weighing the amount of food found in the bowls of the internees, it was found that the figures were much smaller — that is, 1070 to 1109 calories, with an average of 1077 calories daily per person.

These investigations show that the quantitative value expressed in calories never exceeded 1100 calories daily per person and that it ranged between the values of 950 and 1100 calories from October, 1941, through June, 1942.

We have many documents concerning feeding in Germany and the countries invaded between 1914 and 1918. The situation in the urban communities

in those years was considered critical when the daily intake of protein substances dropped to 40 to 50 gm., the daily ration of fats to 20 to 30 gm., and the supply of calories to 1400 to 1800. The average daily ration for an adult was 2232 calories (Loewy's investigation in 1916). German workers received 2200 calories during the first three years of World War I (Lusk and Codville's investigation). The general loss of weight was caused by the reduction in the consumption of fats.

The lowest figures, still well above those observed in the camps, were found in northern France in 1917-1918. They were 1467 calories (Lambling investigation).

Qualitative Value of Food in Camps

In the camps under supervision, the ration of protein substances does not surpass 30 to 50 gm. daily and is almost exclusively of vegetable origin; the actual daily supply of fat is 8 to 10 gm. The nitrogenous and caloric value of the rations distributed in the camps is by no means sufficient to maintain the protein equilibrium of the organism.

Instead of the normal daily ration of 1 gm. of protein per kilogram of body weight, — that is 60 gm. for a person weighing 60 kilograms, — the camp diet contained only 48 gm. of protein of vegetable origin. Furthermore, instead of the daily minimum of 24 gm. of protein of animal origin the maximum was only 15 gm. The result is a continuous deficiency in nitrogen that, even if amounting to only 9 gm. daily, represents a loss of 3300 gm. of protein a year, or a loss of 16.5 kilograms of muscles and visceral tissue for these patients.

The food supply is deficient qualitatively not only from a purely biologic point of view. Other qualitative factors, such as conditions of freshness, conservation and preparation, make the nutritional picture in the camps even worse. Besides, mass feeding does not allow special attention to individual differences or to needs of a particular state of health, and causes inevitable difficulties.

The great monotony of the diet must also be emphasized. It is well known that the ideal condition for the commencement of malnutrition is to stick to the same diet for a long time. The lack of certain vitamins in the diet is sufficient to cause, within a certain time, characteristic hypovitaminoses. This is exactly the case with the internees.

Owing to the purchase of large amounts of a single food product in season, such as cabbages, pumpkins, turnips, Jerusalem artichokes and carrots, the diet remains unchanged for long periods. The same vegetable appears on the table for many consecutive weeks. Improperly preserved, kept in stock for too long, badly prepared and floating in a disproportionate quantity of liquid, this vegetable, poor in vitamins and salts, causes various disabilities associated with hypovitaminosis. Moreover, a con-

siderable number of internees suffered for a long time or are still suffering from acute or subacute intestinal disorders. It is well known that inadequate intestinal absorption can be the cause of hypovitaminosis even if the supply of vitamins is adequate.

Nutritional Situation outside the Camps

We are indebted to the Nutrition Section of the Institute of Hygienic Research of Marseilles (operated under the auspices of the Rockefeller Foundation) for a study of the nutritional condition of the population of Marseilles. The results of the investigation given are those for October–December, 1941, since the figures obtained from more recent investigations are still unavailable. It is for this reason that figures relating to the same period in the camps were given above. Since then the situation in the camps has become aggravated entirely out of proportion to the nutritional restrictions of the people of the country in general.

Quantitative values. The usual average of calories per person daily in the groups studied among the population of Marseilles from February to September, 1941, was 1735 calories for men and women, and 1565 calories for children between the ages of twelve and nineteen. The lowest figures for a few persons with a particularly small ration were 1600 calories for men (in contrast to 2217, the highest figure obtained), 1400 calories for women (in contrast to 1741, the highest figure obtained) and 1400 calories for children between the ages of twelve and nineteen (in contrast to 2097, the highest figure obtained).

For the period October–December, 1941, the figures for all the groups studied are as follows: 1700 calories for men and women, and 1620 calories for children between the ages of twelve and nineteen. The lowest figures found in the case of some persons in particularly bad circumstances are not given, but the figures for the least favored group do not go below 1764 calories for men, 1509 calories for women and 1610 calories for children between the ages of twelve and nineteen. These records give the impression that the nutrition of the people of Marseilles is nearly down to the German nutritional standard of 1917 and in certain respects is even below it.

As regards nutrition in the camps, the rations of the average citizen of Madrid at the end of the siege during the Spanish Civil War (1937–1939) fell to 852 calories from an average of 1514 calories per person at the beginning of the siege (Grande's investigation).

Qualitative values. If the condition of the internees of the camps is compared with that of the population of Marseilles from the qualitative point of view, it is seen that the latter received a daily ration of 65 gm. of protein for the men and 55 gm. for the women. Twenty-eight per cent of this amount was a true protein — that is, 21 gm. of animal protein (October–December, 1941). What is more impor-

tant, this ration succeeded that of February–September, 1941, which without doubt provided for the minimum essential nitrogen. This is not the case with the internees, who have suffered from nitrogen deficiency for the past two years.

Vitamins and Mineral Salts

The daily supply of vitamins and minerals of the internees has not been calculated in detail. Certain considerations, however, permit an evaluation of the situation. The report on the nutritional situation of the population of Marseilles makes it evident

FIGURE 4. Deaths in the Camps during the Last Nine Months.

that there is a lack in the supply of vitamins A, B and C. It is certain, therefore, that the internees in the camps, who receive a diet much poorer in vitamins, suffer an indisputable deficiency in these biocatalysins, a deficiency aggravated by the intestinal disorders prevalent in the camps.

We shall not go into further detail on this question, which has been treated above in the section on hypovitaminosis. Similarly we shall not discuss the starvation that was revealed by the investigation in Marseilles. There was certainly sufficient calcium and phosphorus deficiency in that diet to permit similar conclusions as to the same deficiencies in the camps.

Conclusions

From these comparative studies it may be concluded: that the diet served to the internees in the camps is inferior by 40 to 50 per cent to the diet provided for the civilian population of Marseilles, which, from the point of view of food supplies, is one of the least favored cities in France; that the

prevalence of malnutrition will continue in the camps if the present ration is maintained; and that under the present conditions all effort of the relief agencies to combat malnutrition by an additional food supply and intense treatment with medicines will remain unproductive.

CRITICAL EXAMINATION OF RESULTS

On the whole we may state that the dietary and medical treatment, started in February, 1942, and continued until the present (July, 1942), has en-

through loss of water, and in 8 per cent there was a serious decrease (Fig. 5). Between May 1 and 15, the percentage of the gaining cachectic patients reached 60 per cent and diminished by 17 per cent in the next fortnight. Between June 1 and 15, 51 per cent of the patients gained weight, 19 per cent were stationary, and 30 per cent lost weight, the last being due almost exclusively to the disappearance of edema.

Observations in another camp show the following changes in weight: in March, 27 per cent of the pa-

FIGURE 5. *Weight Changes among Cachectic Patients Supplied with Supplementary Nourishment (Camp Rivesaltes: February 27 to May 12, 1942).*

tirely transformed the appearance and state of health of our patients. After three months' treatment one can witness real restorations to health, especially in cases of the neurologic and mental type. The atmosphere of confidence and optimism that at present pervades the barracks of the cachectic patients, formerly desolate, is deeply moving.

Since March, when efficient services and supplies were provided, cases with fatal outcome have practically disappeared from all the camps (Fig. 4). The patients gained in weight; their strength returned.

From April 16 to 30, 1942, of 100 cachectic patients in a certain camp 32 per cent showed increase in weight; in 20 per cent the weight remained stationary; in 40 per cent the patients lost weight

patients showed decreases, 14 per cent were stationary and 60 per cent gained weight; in April, the respective figures were 18, 18 and 64 per cent; and in May, 49, 18 and 33 per cent. The results in May were much less favorable than those in the previous months, because 79 new patients (25 per cent) coming either from prisons or from the camps had to be admitted either to the hospital or to the barracks, and also, because the insufficiency of the food provided by the camp management reached catastrophic proportions during that month; the basic food was reduced to lettuce and turnips, there being no dry vegetables, potatoes, or noodles. In addition, the use of large quantities of salt fish (salted sardines) by the management caused extensive intestinal disorders, from which the patients recovered

with great difficulty. Nevertheless, 37 cachectic patients (5 per cent) were able to leave the hospital after a two-month treatment and are considered to be out of danger for the time being.

This example of the harmful effect of an insufficient and unbalanced diet is not unique. The insufficiency of the usual fare in the camps should make one cautious regarding long-range prognosis. This alarming situation is evident from the progressive increase in the number of cachectic patients and in the decrease of the convalescents. Cachectic and precachectic patients sent back among the other internees relapse into their former condition, because they are exposed to the very factor that caused their disease — insufficient food. The noncachectic persons in their turn swell the number of the cases of malnutrition after exhausting their reserves and becoming more and more sensitive to the same pathogenic factor — starvation. Thus, men wrested with the greatest effort from the effects of starvation have been granted only a postponement of death.

The basic food, the daily ration furnished by the camp, remains the essential element of rescue for patients suffering from starvation, and it is up to the respective authorities to provide it.

* * *

We know that the victims of the "disease of starvation" in the camps number no more than the loss of a few companies in a skirmish, and that thousands of men fall throughout the world — innocent victims of this global war. But we know also that we have not the right to contribute to the depreciation of the value of human life. Our country will never command enough power over the spirit of man to bear the incalculable consequences of useless and unjustifiable deaths. We demand that the relief agencies continue their efforts on behalf of those interned, cost what it may. We appeal to the heartwarming sympathy of the Inspector General of the camps, who has given evidence on numerous occasions of his desire to increase the efforts intended to obtain an effective control of the sources of supply and their regular distribution to the camp subdivisions themselves. The rescue of the interned population is the prize at stake. In their name we express our deep gratitude to all our friends far and near who, by their constant evidences of sympathy, have allowed them to keep inviolate their confidence in human solidarity and their faith in a more just and generous future.

OBSERVATIONS ON THE MASSIVE-DOSE ARSENOTHERAPY OF EARLY SYPHILIS BY THE INTRAVENOUS DRIP METHOD*

IV. Three Years of Trial

LIEUTENANT BRANCH CRAIGE, JR., M.C., A.U.S.,† AND LIEUTENANT COLONEL JOSEPH F. SADUSK, JR., M.C., A.U.S.†

NEW HAVEN, CONNECTICUT

IN March, 1942, Sadusk et al.¹ reported on a series of 33 patients with early syphilis treated at the New Haven Hospital with massive-dose arsenotherapy by the intravenous drip method. It is now possible to give a further follow-up on these patients, as well as toxicologic and therapeutic observations on 40 more.

Since the introduction of massive arsenotherapy for early syphilis by Chargin, Leifer and Hyman² and their associates, numerous modifications of their methods have been tried. They originally demonstrated that the toxicity of a substance such as an arsenical, intravenously administered, is materially lessened if it is introduced by slow, constant drip rather than in a single large injection. Their successful therapeutic results in syphilis have stimulated many others to adopt the administration of massive arsenotherapy. A list of some of these appears in a recent review article by Reynolds, Mohr and Moore.³

Some of these investigators, however, have used drugs that are more toxic than the recommended Mapharsen (meta-amino-para-hydroxy-phenylarsine-oxide hydrochloride), and some have discounted the rationale behind the slow administration of the drug and have administered large doses by the multiple-syringe method. Toxic reactions encountered with the use of neoarsphenamine or the multiple-syringe technic should not reflect on the value of the constant-drip method with Mapharsen.

TECHNIC

Studies of the patients in this series were made to establish a definite diagnosis of early syphilis and to exclude patients with serious complicating disease. The diseases considered contraindications to massive arsenotherapy were liver disease and severe nephritis — the former because arsenicals are taken up and stored mainly in the liver, and the latter because a rare case of renal damage has been reported.⁴ Gonorrhea is not a contraindication, and 1 of our patients had early tuberculosis and another mitral stenosis and an old hemiplegia. Routine studies in-

*From the Department of Internal Medicine, Yale University School of Medicine, and the Medical Service of the New Haven Hospital. This study was aided by grants from the Clinical Research and Teaching Fund of the Yale University School of Medicine.

†Formerly, instructor in medicine, Yale University School of Medicine.

cluded a blood cell count, serologic examination, urinalysis, nonprotein nitrogen determinations, an electrocardiogram and x-ray examination of the chest. Renal studies were made if nephritis was suspected from the urinalysis, and liver-function tests were made in alcoholic patients.

The actual administration of the drug was relatively simple. Solutions were made up twice daily—1200 cc of 5 per cent glucose in a Genwall flask with 120 mg of Mapharsen. A strip of adhesive plaster on the side of the flask was marked with the levels at which the fluid in the flask should be at various hours. The rate of flow was regulated with reference to the marks, and the more intelligent patients were often able to watch the clock and help regulate the flow themselves. Thus two flasks (2400 cc with 240 mg of Mapharsen) were administered daily over a period of twelve hours for five days, making a total for each patient of 12 gm of Mapharsen. At the conclusion of the period, the blood-cell count, urinalysis, nonprotein nitrogen determination and electrocardiogram were repeated and a lumbar puncture was performed.

Follow up observations were made, when possible, at monthly intervals for six months, and at three month or six-month intervals thereafter. When possible, another lumbar puncture was performed after several months. The co-operation of local and state health officers in helping to bring patients back for follow-up tests has been of great value.

Table 1 classifies the patients in the series. For the purpose of studying the toxicologic phenomena it is convenient to note that there are eighty treat-

weeks of routine therapy elsewhere after leaving our observation. Another had a single injection of bismuth.

Toxicology

The toxicologic data are summarized in Table 2. Primary fever (Herxheimer reaction) occurred in many of the patients, sometimes with a shaking chill

TABLE 2 Toxic Phenomena in Eighty Courses of Treatment

It was often accompanied by a macular eruption, especially in the late primary and secondary cases. It usually appeared six or eight hours after the beginning of treatment and subsided a few hours later. In no case was treatment interrupted because of this reaction.

Secondary fever (drug fever), with or without a cutaneous eruption, appeared in many of the cases on the fourth to the sixth day after the beginning of treatment. In 1 case a shaling chill occurred with the fever. Like the Herxheimer reaction, these symptoms disappeared without treatment. The rash was fairly uniformly a fine maculopapular, brightly erythematous eruption of generalized distribution. It was not hemorrhagic, and exfoliation did not occur. Only rarely did pruritus accompany it.

Vomiting occurred in most cases, being a prominent symptom on the afternoon of the first day. As previously pointed out,¹ it was more frequent and of greater severity in women than in men.

Most patients complained of some pain along the course of the vein receiving the infusion. Usually this pain could be satisfactorily controlled with small doses of codeine. Thrombosis of one or more of the veins occurred often but aside from local tenderness led to no difficulty. In most cases recanalization in these veins took place during subsequent weeks.

Leukopenia was a rare occurrence and was not accompanied by granulocytopenia. A mild secondary anemia was frequently noted during the follow-up period. In most patients no symptoms were referable to the anemia, which subsided without therapy.

ment courses, whereas for evaluating the therapeutic results there are 74 patients, inasmuch as 7 patients were treated twice and 1 of these having a proved reinfection was counted as 2 patients. His case history was previously reported in detail¹

Nineteen patients had had previous antsyphilitic therapy, either bismuth or an arsenical, but in no case had more than two routine injections been given. One patient was inadvertently given several

Some noted a feeling of tiredness or weakness for two or three weeks.

Electrocardiographic changes⁵ consisted of diminution of the amplitude of the T waves in any or all leads. If the T waves were low at the beginning of therapy, inversion frequently occurred. Such changes disappeared during the first three weeks of the follow-up period, and during the second course of treatment; there was significant depression in only 1 of 3 patients.

During the second or third week after completion of treatment, evidence of peripheral neuritis was noted in nearly half the patients. In most of them it amounted only to numbness and tingling of the toes or rarely of the fingers. This subsided in a few days. A few patients also had definite stocking-type hypesthesia to pinprick. Some, in addition, lost the ankle jerk.

All the above phenomena are considered to be fairly benign accompaniments of treatment. Some are annoying and some cause pain or distress, but none represent cause for alarm.

Of the more serious toxic phenomena, only motor neuritis and jaundice have occurred in this series, and in only 1 case. This patient recovered. Treatment in her case probably represented an error in judgment, since it is likely that she had hepatitis before treatment and was consequently unable to excrete the large doses of Mapharsen. It is for this reason that we hesitate to administer the treatment to any patient with fever unless liver disease can be excluded by appropriate tests.

No patient has had a nitritoid crisis, nephritis, cerebral symptoms, hemorrhagic encephalitis or exfoliative dermatitis, and there have been no fatalities.

THERAPEUTIC EFFECTS

The local primary and secondary lesions became negative on dark-field examination within twenty-four hours from the beginning of treatment. Before the five days were completed there was usually clear evidence of epithelialization and shrinking of the chancre or condyloma. Skin rashes faded more slowly if pigmentation had occurred.

Reversion of the serologic reaction to negative usually occurred during the first six months following therapy, and in most cases between the tenth and twentieth weeks, as shown in Figure 1, which records the rate of reversal in 48 cases in which there has been time for them to become seronegative. In interpreting this figure it should be recalled that in most cases observations were made not oftener than once a month and that, therefore, the elapsed time shown tends to be longer than the actual time of reversal.

In the total series of 72 cases, in which, as stated, 1 patient who was reinfected and treated twice was counted as 2 patients, 36 have been followed for less than six months. (Table 3). Five of these when

treated had primary syphilis with a positive dark-field and a seronegative reaction. These 5 patients, and 12 who were originally seropositive, were seronegative when last seen. Two have had doubtful reaction and 17 are still seropositive, but they must be observed longer before it can be determined whether one course of treatment will cause reversal of the serologic reaction.

There remain 38 patients who have been observed for more than six months (Table 3). Thirty of these became seronegative after one course of

FIGURE 1. *Time of Reversal of the Serologic Reaction.* This chart includes the 48 patients whose serologic reactions became or remained negative after one course of treatment. The curve indicates the cumulative number of seronegative patients at various times during the first year of observation after the administration of massive arsenotherapy.

massive arsenotherapy and have remained so to date. One additional patient became seronegative but relapsed. Seven remained seropositive. The patient who relapsed and 5 of the 7 who remained seropositive, as well as the patient who was reinfected, were given a second course of massive arsenotherapy. The diagnoses at the time of re-treatment are listed in Table 1. Re-treatment is customarily recommended if the serologic tests remain positive after six months of observation or if a relapse or re-infection has occurred.

Following the second course of treatment, both the patient who was reinfected and the one showing a serologic relapse became seronegative. Of the 5 re-treated patients who remained seropositive after the first treatment, 1 has remained seropositive for more than six months after the second treatment and represents an unquestioned serologic failure; 2 are now seronegative, and 2 have not been followed long enough after the second course to determine whether re-treatment will be successful. Two of the 7 patients who remained seropositive after the first treatment have not yet been re-treated. There remain, therefore, 5 of the 38 who have been followed more than six months who are still seropositive, whereas 33 are now seronegative. It should be emphasized, however, that of these 5 patients none show clinical evidence of syphilis and 4 have had

negative spinal-fluid Wassermann reactions. One has had a positive or doubtful spinal-fluid reaction — a twenty-one-year-old seropositive man who had a chancre and a positive dark-field test. Thirty-six weeks after massive arsenotherapy the spinal-fluid Wassermann reaction was negative. Because the patient remained seropositive, however, he received a second course of massive arsenotherapy after fifty-nine weeks. At seventy-one weeks, when he was still seropositive, the spinal fluid gave a positive

limited to the 1 patient with jaundice, severe anemia and motor weakness, who recovered.

This method is not a cure-all for syphilis. We have attempted its use in no patient with latent syphilis unless the secondary eruption was known to have recently been present. Consequently we have no experience in its use in late syphilis. In early syphilis its therapeutic effects as presented above are probably comparable to those obtained with a year and a half's uninterrupted weekly injections by the alter-

Wassermann reaction in two laboratories and a negative one in a third. The globulin test was negative, the colloidal-gold curve was 0000000000, and the spinal fluid showed 11 lymphocytes per cubic millimeter.

The spinal fluid was examined at the time of treatment in 61 cases, and in 58 of these the Wassermann reaction was negative. In 3 cases it was positive at the beginning of treatment, and in 2 of these it

nating block method. One advantage, of course, lies in the fact that every patient completes a full course of treatment, whereas in patients with early syphilis who enter a course of a year and a half's weekly injections, not more than 16 per cent actually receive an adequate minimal course of therapy as defined by the United States Public Health Service.⁷ A second advantage is that the patient is kept in the hospital while infectious and that when he is

subsequently became negative. The third patient has not had a second lumbar puncture. In 38 cases the spinal fluid was examined during the follow-up period, usually after six months but sometimes earlier. In every case except the one mentioned above, the follow-up spinal-fluid Wassermann reaction was negative (Table 3).

Table 4 shows the results of pregnancy in several cases.⁸

DISCUSSION

It is apparent from the foregoing data that minor discomforts and inconveniences during and immediately after a course of massive arsenotherapy by the continuous-drip method are frequent. Serious toxic phenomena were rare in this small series, being

returned to the community he is, and almost invariably remains, noninfectious.

The cost of massive arsenotherapy by the intravenous drip method varies in different communities. Many of the diagnostic procedures we have done are probably unnecessary except for research purposes. The following steps appear to be essential, and from this list the cost may be calculated: seven to ten days of hospitalization (those who have secondary fever remain a little longer than the others); physician's history, examination and observation; at least two serologic tests; a dark-field examination, a blood-cell count, two urinalyses and, occasionally, a nonprotein nitrogen determination and a bromsulfalein, cephalin-flocculation or other liver-function test; materials for infusion (5 per cent

glucose, Mapharsen and equipment); facilities for obtaining serologic tests, preferably once a month for six months and less often thereafter; and lumbar puncture after six months.

SUMMARY

Massive arsenotherapy for early syphilis has not as yet in our limited experience proved hazardous, and presents no great difficulties in administration. The cardinal points to be observed are as follows: establishment of the diagnosis of early syphilis; exclusion of patients with fever, liver disease or severe nephritis; and periodic follow-up visits with determination of whether re-treatment is necessary on the basis of the serologic reaction six months later, or of relapse at an earlier date.

Its virtue lies in the facts that every patient receives an amount of treatment that has been found sufficient for cure in four fifths of the patients; that completion of a minimum adequate amount of treatment does not depend on the patient's returning; and that when the patient leaves the hospital he is noninfectious and in almost every case remains so. Its disadvantage lies in the danger of an occasional severe toxic reaction that may rarely be fatal.

Using massive arsenotherapy by the five-day continuous intravenous drip method satisfactory

results were obtained in 79 per cent of the cases observed six months or more. By re-treating selected cases, the total of satisfactory results has been raised to 87 per cent. Of the remaining 13 per cent, some patients have not been observed long enough after re-treatment to ascertain the final result. Except for a positive spinal-fluid reaction in 1 case, the only evidence of syphilis in these cases is the positive serologic reaction.

MEDICAL PROGRESS

PHYSICAL THERAPY IN GENERAL MEDICAL PRACTICE*

ARTHUR L. WATKINS, M.D.†

BOSTON

IN PREVIOUS reports on physical therapy there have appeared general reviews and summaries limited to the application of physical measures in the treatment of diseases of the nervous system and conditions commonly encountered in surgical practice.¹⁻⁴ The present addition to the series is restricted to a review of the recent literature relating to the physical-therapy procedures found to be of value in general medical practice.

Neurologists, surgeons and particularly orthopedists have long recognized the value of physical therapy in dealing with conditions affecting locomotion, but the internist has less frequently understood and employed these methods. As explained by Piersol,^{5, 6} this is due to lack of adequate medical education in this field and insufficient training to develop skill in application. The public, however, has remained aware of the benefits of physical

treatment and often seeks it from nonmedical sources when denied it by physicians. Those procedures, therefore, that the general practitioner should find useful will be described in relation to their employment in the treatment of common disorders of the various systems of the body.

CHRONIC ARTHRITIS AND ALLIED DISORDERS

Rheumatoid arthritis is the outstanding example of a medical condition in which the proper use of physical measures is of value. In fact, Short and Bauer⁷ state that physical therapy cannot be dispensed with in the treatment of this disease. They further assert that "general measures — including rest of the whole patient and of the joints, along with an attempt to preserve, so far as possible, the function of the articulations and muscles — form the backbone of the treatment of rheumatoid arthritis." At the Robert Breck Brigham Hospital training in body mechanics has been emphasized as being of prime importance in combating the

*From the Department of Physical Therapy, Massachusetts General Hospital.

†Assistant in medicine, Harvard Medical School; director of Physical Therapy Department, Massachusetts General Hospital.

tendency toward joint deformities and in lessening the strain on damaged joints.⁸ Postural exercises are at first taught in the supine position. They include deep breathing, rib stretching, contraction of the abdominal and gluteal muscles or the so-called "pelvic tilt." Later, when more activity is allowed, exercises in sitting and standing positions are performed and the proper mechanics of walking are taught.

In order to improve individual joint function, a combination of physical measures are indicated, including thermotherapy, massage, splintage and exercise. Heat is used to increase local circulation, lessen sensitivity and aid in muscular relaxation before exercise.⁹ Radiant-heat cradles or bakers with four 60-watt or 120-watt bulbs may be used, or for home use a single 250-watt clamp lamp, and 500-watt or 1000-watt units in hospitals.¹⁰ Treatments should last from thirty to forty minutes and be given once or twice daily. Moist heat may be applied in the form of hot fomentations. Melted paraffin wax baths are an especially effective method of applying heat to the extremities.¹¹ These baths consist of a mixture of 7 parts paraffin wax to 1 part paraffin oil, which is kept at the melting point (approximately 125°F.) in a double boiler or an electrically heated unit. The extremity is immersed and quickly removed six to eight times until a coating of wax is formed like a glove, after which it may remain in the bath for twenty to thirty minutes. After the treatment the wax easily peels off and may be used again. Warm whirlpool baths in addition to heating effects also provide mild stimulative massage and an opportunity for underwater exercise. Large Hubbard tubs allowing movement of the shoulders and hips under water are extremely valuable, although of course available only as hospital installations. Therapeutic pools may also be utilized to advantage by arthritic patients, particularly when beginning to walk. In the home a daily hot bath or shower is often of value. A safe bath temperature to begin with is 100°F., which may be increased as tolerated. The length of the bath may be gradually increased up to thirty minutes. In an occasional patient, contrast baths appear to give more relief of pain than does the use of heat alone. In this procedure the temperature of the hot water is 100 to 110°F. and that of the cold 60 to 65°F. Seven alternate immersions are recommended, with five minutes in the hot bath and two in the cool, always starting and finishing in the hot bath.⁹ Diathermy may occasionally be employed, particularly for hospitalized patients, but simpler methods that can be used repeatedly with little expense are usually more suitable. Electric heating pads are used extensively by patients, although they frequently become too hot and may cause burns.

Iontophoresis, using drugs such as NiccholyI or histamine, is often useful in securing a hyperemia that is somewhat more persistent than that following

heat, but this is not recommended as a routine procedure.¹²⁻¹⁴

General ultraviolet irradiation in mild, graduated doses may act as a stimulant to appetite and a sense of well-being, but has no known specific effect on the disease. Controlled heliotherapy may be administered for the same purpose, with avoidance of overexposure.⁷

Fever therapy is often of benefit in selected cases.¹⁵ Krusen⁹ has recommended short sessions of about thirty minutes at 101°F. Fever may be produced by use of a fever cabinet or by a full tub bath at a temperature of 98 to 105°F.

Massage is a useful and often neglected procedure that aims to increase local circulation and improve muscle tone. It may advantageously follow thermal applications and precede therapeutic exercises. As a rule only gentle stroking and kneading motions are to be used and direct movements over the joints are avoided, particularly during the stage of acute inflammation.¹⁶

Therapeutic exercises are the most important single physical measure used to improve joint function, although most effective when combined with heat and massage. The active co-operation of the patient is essential for obtaining satisfactory results in mobilizing joints and maintaining musculature. During the early acute stages of inflammation, static or muscle-setting exercises only are used. Active exercises are then carefully graded in intensity; at first they may consist of active assisted motions, and later of voluntary exercise. Resisted exercises are rarely indicated because of the tendency toward subluxation. Passive stretching or manipulation to increase the range of joint movement is also dangerous. Under careful supervision the patient can usually be taught how to stretch the joints actively in correct positions and how to judge the forcefulness of the efforts according to the degree of subsequent reaction, which when consisting of pain or muscle spasm should not last more than an hour or two. The specific joint exercises are to be repeated by the patient on an average three times each day and must be checked by the technician every day at first, and less often when the routine is well learned.

In many cases of rheumatoid arthritis, deformities of joints are present that require special orthopedic attention for correction. The commonest of these are flexion contractures of the knees and hips and the characteristic combination of flexion, hyperextension and ulnar-deviation deformities of the hands. Traction, specially designed splints or a progressive series of casts have been described for correction and prevention of these deformities.^{17, 18} It is particularly important whenever any immobilizing apparatus is used in these cases that periods of carefully administered physical therapy be provided to prevent ankylosis. The details of the combination of orthopedic and physical therapeutic

measures have been well described by Kuhns¹⁹ in his section of Steinbrocker's textbook on arthritis.

Since rheumatoid arthritis has a well-known tendency to chronicity, physical measures that can be utilized in the home repeatedly each day are to be recommended. Recently Treusch and Krusen²⁰ reported a survey of home physical therapy in 229 cases of arthritis, and found that 93 per cent of the patients followed the instructions for home therapy and 65 per cent continued them for three months or longer. They observed that patients with more than one course of instruction were more likely to carry on. Four fifths of the patients were definitely benefited, and two fifths were enthusiastic over the regime.

In hospitals, occupational therapists may assist in the instruction and supervision of patients in exercises or activities designed to improve joint range and muscular strength. This functional type of occupational therapy may be advantageously co-ordinated with physical-therapy treatments. Such co-ordination is best achieved when the physical and occupational therapy departments are directed by a physician specializing in physical medicine.²¹

Physical therapy is of definite value in the treatment of degenerative joint disease or hypertrophic arthritis (osteoarthritis). Moderate heat applied locally and repeated several times daily is effective in relieving pain.²² The methods previously described are satisfactory. Gentle sedative massage, chiefly stroking and light kneading, assists in reducing muscle spasm and pain. Rest of painful joints during the presence of acute symptoms is usually indicated,²³ but is not so prolonged as in rheumatoid arthritis, for the pathologic changes are in the nature of degeneration or aging processes rather than progressive inflammation.²⁴ It is important to maintain the supporting musculature by means of graded active exercises without weight-bearing or resistance, thus avoiding further traumatic effects on the joints. Teaching the principles of correct body mechanics is of prime importance in order to relieve weight-bearing joints of unnecessary strain. Elderly patients with degenerative disease of the joints are frequently found to have osteoporosis of the spine and disabling pain. Black, Ghormley and Camp²⁵ have reviewed a small series of these cases and discuss the differential diagnosis and possible etiologic factors. They recommend the administration of an adequate diet together with additional calcium and phosphorus and vitamin D. For relief of pain short periods of bed rest and local heat followed by sedative massage were found to be effective.

The role of physical therapy in the treatment of infectious arthritis is secondary to the specific measures available.²⁶ In tuberculous arthritis, healing of the local lesion is generally achieved only by ankylosis, so that heat, massage and exercise are contraindicated. General heliotherapy is, however, of

recognized value in curing the disease process systematically, when used in conjunction with rest and hygienic management, particularly in a sanatorium. Artificial sources of ultraviolet radiation may be used if the climate does not permit direct exposure to the sun. Overdosage must be especially guarded against, and in the presence of active progressive pulmonary lesions all irradiation may have to be omitted.²⁷

Gonorrheal arthritis usually responds well to sulfonamide medication or penicillin. In drug-resistant cases good results from combined drug and fever therapy are reported.^{28, 29} The management of artificial fever requires exact technic and experienced personnel. Hospitalization is essential, and the technics to be used are well established.³⁰ The joints that are acutely inflamed are kept at rest, and no attempts at mobilization are begun until the inflammatory process has subsided. At that time mild heat to improve the circulation and graded active exercise usually suffice to restore full joint function in those cases that are promptly and adequately treated medically. In other types of septic arthritis the end results are dependent on control of the infection by the chemotherapeutic measures available, together with surgical drainage in some cases. Physical therapy aids in overcoming the limitation of motion secondary to immobilization and is begun only after subsidence of the septic process. There may be danger in beginning mobilization too early in these cases because the action of the chemotherapeutic agent may mask the degree of inflammation still present.

Hemophilic arthritis associated with an acute hemarthrosis is often very painful and destructive. These joints should be treated by immobilization, physical therapy being ordered only when the bleeding has stopped and the acute inflammatory reaction has subsided.²⁶ Gentle effleurage and adequate assisted active exercise may then be begun, passive stretching or manipulation being avoided.

Anaphylactic arthritis occurs as a manifestation of serum sickness, and as it is self-limited rarely requires any physical therapy other than heat for relief of pain. Neuritis is a somewhat uncommon complication of serum sickness, but may result in paralysis and atrophy of one or more of the shoulder-girdle muscles, particularly the deltoid, trapezius and serratus magnus.³¹ Although the prognosis for eventual recovery in these cases is good, there is a period of six to twelve months of limited shoulder function and pain during which the patients may be benefited by physical therapy. Mild heat and sedative massage are administered for relief of pain and muscle spasm of the surrounding musculature, which is subjected to unusual strain in moving a partially paralyzed extremity, and the atrophied muscles are benefited by electrical stimulation to lessen the degree of wasting and to hasten functional return after neural regeneration.³²

Another type of cervicobrachial neuritis may result from neurocirculatory compression in patients with a tight or spastic scalenus anticus muscle. According to Spurling and Grantham,³³ about 75 per cent of these patients with painful arms and shoulders improve or become asymptomatic after conservative treatment. Hansson³⁴ is of the same opinion and had described in detail corrective postural exercises for the neck and shoulder-girdle musculature. Local application of heat over the scalenus muscle and sedative massage are also advised.

Radicular type of pain in the same location may be associated with osteoarthritis of the cervical portion of the spinal column.³⁵ According to McFarland and Krusen,³⁶ traction with the Sayre head sling usually gives relief. They advocate radiant heat and massage prior to the traction, which is given in the sitting position with a slowly increasing force up to 70 pounds, as tolerated. The head is then slowly rotated and the traction gradually released. Treatments are repeated twice daily for a week or more.

Myalgia of the cervical muscles is another fairly common condition that responds to treatment by physical agents.³⁷ This is sometimes described as an "indurative" headache or as cervical fibromyositis. Minor epidemics have been reported from England and in the armed forces.³⁸⁻⁴⁰ The etiologic factors are not clear. The predisposing factors include occupational strain or poor posture, resulting in fixation of the head and neck in abnormal alignment, vasomotor imbalance and exposure to cold and drafts. In many cases hypersensitive areas are found in muscles and in palpable thickening or localized areas of muscle spasm.⁴¹ Copeman⁴² in a discussion on the etiology of these so-called "fibrositic nodules" observed, that they may appear in the course of infectious diseases such as influenza and may be reactivated by exposure to cold or by trauma and subsequent sepsis and may form the basis of rheumatic syndromes in later life. Treatment of these patients is often highly dramatic in its results. In some patients with acute stiff neck, complete relief is obtained by fifteen minutes of head traction. Other patients respond as readily to local application of heat with infrared radiation or diathermy, followed by stimulation of the muscles in spasm with a sinusoidal current. For patients with more persistent symptoms, Krusen has described the physical therapeutics of fibrositis.⁴³ Procedures to be used are local heat, special friction massage and stretching exercises. The patients are frequently neglected by physicians unacquainted with the procedures of physical medicine, and they turn to the osteopath or chiropractor for relief that could be obtained by recognized methods of treatment. Manipulation of joints is likewise for the most part neglected by the medical profession, chiefly because of the exaggerated claims made by bone setters and others, based on erroneous diagnosis and unscien-

tific analysis of results. Recently Fredette⁴⁴ has presented the indications and contraindications to manipulation and has described the technic of the maneuvers and the aftercare of patients. Intelligently and skillfully used on properly selected patients, manipulation has a definite role as a procedure in medical therapeutics.

The diagnosis and treatment of patients with complaints of backache and painful feet is a difficult and important subject, particularly in the armed forces and among civilians now leading a more active life than customarily. Orthopedic surgeons are usually called on to care for these patients, and the details of methods used in differential diagnosis and in treatment are beyond the scope of this paper. The internist should, however, be familiar with the management of patients with chronic postural strain, which is the commonest cause of backache.⁴⁵ In these cases physical therapy is of cardinal importance, as has been pointed out by Krusen.⁴⁶ Local application of heat, skillfully administered massage and postural and corrective exercises alleviate symptoms in a large percentage of cases, and Jostes⁴⁷ has shown how manipulation may be of value. Nutt⁴⁸ has written an excellent article on painful feet, outlining for the practicing physician the anatomy of the foot with reference to proper bony and muscular alignment and the prevention and treatment of the common varieties of foot complaints. Other articles dealing more with physical therapy in these conditions have appeared.^{49, 50}

DISEASES OF BLOOD-FORMING ORGANS

Ultraviolet rays are the chief physical agent reported as having a favorable influence on some types of anemia. In secondary anemia this effect is limited, nonspecific and far less efficient than are dietetic and drug treatments.⁵¹ A few cases of thrombocytopenic purpura have been improved by carbon-arc radiation.⁵¹ Apperly⁵² has noted an apparent relation between solar radiation and pernicious anemia, finding that the mortality of this disease is inversely proportional to the effective radiation. Peripheral neuritis⁵³ or combined-system disease as a complication of pernicious anemia often requires prolonged periods of muscle re-education, in addition to adequate replacement therapy during rehabilitation.⁵

The influence of ultraviolet irradiation on resistance to infection is controversial and doubtful. Some beneficial action on wound healing has been shown by exposure to solar radiation, including ultraviolet, visible and infrared wave lengths.⁵⁴

ENDOCRINE AND METABOLIC DISORDERS

In a limited number of cases physical therapy is of value in diseases of the endocrine glands and in disorders of metabolism. Gout because of its interference with joint function is a disease in which some symptomatic relief may be obtained by physi-

DISEASES OF BLOOD-FORMING ORGANS

Ultraviolet rays are the chief physical agent reported as having a favorable influence on some types of anemia. In secondary anemia this effect is limited, nonspecific and far less efficient than are dietetic and drug treatments.⁵¹ A few cases of thrombocytopenic purpura have been improved by carbon-arc radiation.⁵² Apperly⁵³ has noted an apparent relation between solar radiation and pernicious anemia, finding that the mortality of this disease is inversely proportional to the effective radiation. Peripheral neuritis⁵⁴ or combined-system disease as a complication of pernicious anemia often requires prolonged periods of muscle re-education, in addition to adequate replacement therapy during rehabilitation.⁵

The influence of ultraviolet irradiation on resistance to infection is controversial and doubtful. Some beneficial action on wound healing has been shown by exposure to solar radiation, including ultraviolet, visible and infrared wave lengths.⁵⁴

ENDOCRINE AND METABOLIC DISORDERS

In a limited number of cases physical therapy is of value in diseases of the endocrine glands and in disorders of metabolism. Gout because of its interference with joint function is a disease in which some symptomatic relief may be obtained.

cal means. During the acute attack, rest is essential, and the pain may be diminished by use of hot compresses or in other cases with cold applications.⁵⁵ In the intervals between attacks and during recovery from the acute episodes, mild heat and graduated exercises to maintain and improve musculature are of value. Medicinal therapy is of the greatest importance, and several recent reviews^{55, 56} have adequately discussed it.

Exercise is known to improve the sugar tolerance of diabetic patients when participated in to the proper degree. According to Drury et al.,⁵⁷ experimental studies have shown that heavy exercise reduces the ketosis in guinea pigs and man. The help of a physical therapist, however, is usually not needed in supervising exercise for diabetic patients. Neuritis may be an extremely painful complication of diabetes; these patients are benefited by local hot applications or radiant heat. In the event of pronounced muscular weakness, muscle re-education in the form of specific strengthening exercises may be indicated.³

Obese patients are frequently referred to physical-therapy departments for measures to reduce weight. Passive procedures such as massage or vibration, although popular with the laity, do not remove fat deposits. Dietotherapy is of fundamental importance, but often exercise is prescribed in addition, to increase the caloric requirements of the body at the same time avoiding if possible increase of appetite. Heat treatments, such as cabinet baths or steam baths, temporarily reduce weight through dehydration but are not of permanent value. Cawadias⁵⁸ maintains, however, that obesity is often not controlled by thermodynamic considerations alone, and recommends that the psychologic reactions of the patient be taken into account. He believes that a combination of therapeutic procedures, including so-called "tonic dosage" of ultraviolet rays or hydrotherapy aimed at improving the psychologic balance, is most satisfactory.

Billig⁵⁹ suggests that dysmenorrhea may be secondary to tightness of ligamentous structures concerned with pelvic motion in patients with postural defects. The cyclic nature of the pain is explained by restrictions of the posterior pelvic tilt, dependent on the estrogenic level. He has found that specific stretching exercises are curative in these cases.

Although some experimental studies have indicated that estrus is influenced by artificial illumination in animals,⁶⁰ little is known at present of practical importance concerning physical agents in the treatment of other endocrine disorders.

PULMONARY DISEASE

Short-wave diathermy is used at times as an adjunct in the treatment of acute or chronic bronchitis and in pneumonia, but in view of modern chemotherapy it seems to have a very minor role. Symptomatic relief of pleuritic pain has, however, been

reported.⁶¹ Its possible usefulness in the treatment of atypical or virus pneumonia is worthy of investigation. Special breathing exercises are of value in relieving dyspnea in asthma,⁶² and preliminary reports indicate favorable results with ultraviolet blood irradiation and with artificial-fever therapy.^{63, 64} Reports have been made of successful treatment of pulmonary abscess by short-wave diathermy, but its real worth is doubtful.⁶⁵ Postural exercises are, however, of value in the prevention and treatment of scoliosis secondary to lung abscess, empyema and thoracoplasty.⁶⁶ In uncomplicated pulmonary tuberculosis, heliotherapy is indicated only after prolonged treatment with rest and hygienic and dietetic treatment, and never in the exudative type. Exposure is carefully graded in the early morning and late afternoon.²⁷ Extrapulmonary complications, however, are favorably affected. Graded exercises and occupational therapy have also a definite place in the convalescence of patients with tuberculosis.^{67, 68}

HEART DISEASE

The rehabilitation of many cardiac patients may be facilitated by suitable physical therapy. Parsons Smith⁶⁹ has described the principles involved and methods to be used. He states that the value of exercise in these patients is based on the improvement of myocardial efficiency from increased stroke volume and venous return. The exercise must be suitable, frequently in the form of occupational therapy. Light general massage may precede exercises, which are at first passive and limited to the large joints, with graduation to resistive exercise walking⁷⁰ and games or activities. The general rule are as follows: no extensive, sudden or prolonged exertion of muscle groups should be allowed; undue exposure or athletic tests should be avoided; exercise should be regulated according to the patient's tolerance; and a suitable occupation in view of the cardiac reserve and the patient's natural inclinations should be found.

Disabilities of the shoulder or hand may occur as a complication of coronary occlusion. Askey⁷¹ believes that this is due to a disturbance of the sympathetic nerves from myocardial ischemia together with an underlying latent arthritis. In his experience the condition was self-limited and treatment was of little avail, although massage was sometimes beneficial. Johnson⁷² has reported changes resembling sclerodactylia following myocardial infarction, and Kehl⁷³ noted Dupuytren's contractures as a sequel to disease of the coronary arteries. These authors also think that the etiologic factor is related to irritation of the sympathetic nervous system and noted little benefit from the usual physical-therapy procedures.

Smith and Kountz⁷⁴ observed 15 patients with anginoid pain of a character suggesting heart disease but actually due to deformities of the

thoracic spine. Postural correction by therapeutic exercise was found to lead to improvement or cure of the symptoms.

DISEASES OF EYE, EAR, NOSE AND THROAT

Otolaryngologists frequently recommend the use of physical-therapy procedures in the treatment of infections of the sinuses, ears and upper respiratory passages,⁷⁵ and a textbook has been devoted to this single aspect of therapy.⁷⁶ In uncomplicated acute upper respiratory infections, especially with involvement of the sinuses, applications of heat are at least of symptomatic value. Infrared generators or short-wave diathermy may be used in conjunction with rest, vasoconstrictors and chemotherapy.⁷⁷ It has been pointed out by Brighton, Snow and Friedman,⁷⁶ however, that short-wave therapy should not be considered in any sense a specific curative agent. They found that it was most beneficial in relief of headache in chronic nonpurulent sinusitis. Teed and Kraus⁷⁹ have studied the problem of dosimetry in ultra high-frequency diathermy and have described an instrument that can be used to measure the dosage of energy applied to the sinuses, whereas in the usual application the technician must be guided almost entirely by the subjective response of the patient.

Williams and Elkins⁸⁰ have described a syndrome that they designate as "myalgia of the pharynx." This is characterized by chronic sore throat, pain on swallowing and occasional attacks of hoarseness, without inflammation of the mucous membranes of the upper respiratory tract. The diagnosis is made by finding on palpation points of tenderness localized in the pharyngeal and laryngeal musculature. These writers comment on possible etiologic factors and recommend certain physical-therapy procedures in treatment. These consist in the use of local heat in the form of short infrared irradiation, diathermy and hot fomentations. Massage, however, is the most effective single agent in treatment and is of a heavy-friction type rather than stroking or kneading.

Ultraviolet irradiation is of proved therapeutic value in lupus vulgaris of the ear and nose and in tuberculous infection of the larynx. Galvanism in the form of ion transfer is sometimes used with zinc sulfate in chronic suppurative otitis media and in allergic rhinitis.⁷⁶

Wiener⁸¹ has written on the use of electrotherapy in ophthalmology. Beneficial effects of diathermy on experimental sepsis were noted, and iontophoresis with adrenalin and Methylol were reported as of value. Wiener also describes the deleterious effects of ultraviolet irradiation on the cornea, and explains the action of different wave lengths on the cornea, lens and aqueous and vitreous humors in relation to the relative absorption and transmission.

DISEASES OF SKIN

In the treatment of cutaneous disorders ultraviolet irradiation is the most familiar physical-

therapy measure. Although this source of energy has been used empirically for almost every type of skin rash, it has been found to be of value in a limited number of conditions and to be distinctly deleterious in others. Cipollaro⁸² and Beaumont⁸³ have recently summarized the beneficial effects of irradiation in diseases of the skin. An authoritative review of the subject of ultraviolet therapy has been issued by the Council of Physical Therapy of the American Medical Association.²⁷

The consensus is that ultraviolet irradiation is of definite value in the treatment of a number of dermatoses in conjunction with topical application and general measures. Patients with acne vulgaris are benefited by erythema doses of artificial ultraviolet rays once or twice a week. More vigorous treatment may be necessary in chronic deep-seated pustules and cystlike lesions. In these cases irradiation with pressure from an air-cooled or water-cooled lamp may be used. Ultraviolet irradiation is often used for furunculosis or other pyogenic disorders, but there is no conclusive evidence of any great benefit. It has also been found to be of little value in the treatment of fungus infection. In psoriasis, general body irradiation speeds resolution of the lesions. The combination of tar and ultraviolet irradiation, as recommended by Goeckerman,⁸⁴ has given better results than has the use of the latter alone. This consists in applying a 3 per cent crude-coal-tar ointment at night. The next morning the ointment is wiped off. This is followed by irradiation of the whole body, after which a bath may be taken. When possible the treatment is given daily with a graduated dosage.

Lupus vulgaris is definitely benefited by ultraviolet rays. A combination of local and general irradiation yields the best result. The concentrated carbon arc employed by the Finsen method or compression with a cooled arc lamp is satisfactory, for local use and heliotherapy or an air-cooled quartz-mercury arc lamp for general irradiation.

Regarding the undesirable effects of ultraviolet rays, it is to be noted that patients with lupus erythematosus may be photosensitive and that cases have been reported of the precipitation of disseminated lupus erythematosus by ultraviolet irradiation, with alarming results. Many acute and subacute inflammations may also be made more acute or caused to spread by too vigorous ultraviolet treatment. Some patients are light-sensitive and exposure may produce eruptions such as hydroa vacciniforme and urticaria.⁸⁵ The presence of porphyrin, certain dyes and sulfonamides may also cause photosensitivity. The present knowledge of unusual light reactions has been authoritatively presented in a monograph by Blum,⁸⁶ one of the leading investigators in this field.

Blum⁸⁷ has also written an interesting and factual article on the military aspects of sunburn. The physical and meteorologic factors involved are

EDITH E. PARRIS, *Assistant Editor*

CASE 30111

PRESENTATION OF CASE

A forty-six-year-old housewife was admitted to the hospital because of abdominal pain.

The history was unsatisfactory because of language difficulty. She was said to have had asthma for years. About twenty months before entry, following her son's enlistment in the Army, she began to "go to pieces" and soon became weak and was forced to go to bed. She was admitted to a community hospital on two occasions within a period of several weeks, because of difficulty in getting her breath, epigastric pain and weakness. She was told that she had heart trouble. She then entered another hospital, where she was treated for "congestive failure, bronchial asthma and chronic bronchitis." She was discharged against advice on the seventh hospital day. She remained at home for three weeks, during which period she was nauseated, vomited a "good bit of her ingested food," had difficulty in getting her breath and was bedridden. The upper abdominal pain continued. She had blood-tinged sputum on several occasions. There was a weight loss of several pounds over a period of months. There was no history of malaria, typhoid fever, dysentery, rheumatic fever, pneumonia, tuberculosis or diabetes.

Physical examination showed a pale woman in moderate distress. The heart was enlarged. The left border of cardiac dullness was 10 cm. to the left of the midline in the fifth space, the right border 2 cm. to the right of the midsternal line. The rate at times was regular, but there were irregularities, which may have been extrasystoles or due to fibrillation. There was a pulse deficit of 12. The pulmonary second sound was greater than the aortic. The lung fields were resonant, with a prolonged expiratory phase and an inspiratory wheeze. The abdomen was protuberant, and there was shifting dullness in both flanks. A tender mass was felt in the right upper quadrant that extended a hand-breadth below the costal margin and merged with the liver. A hiatus hernia was noted in the rectus sheath underlying the umbilicus. There was slight pitting edema of the lower legs and sacrum.

*On leave of absence.

The blood pressure was 148 systolic, 100 diastolic. The temperature was 99.6°F., the pulse 120, and the respirations 28.

Examination of the blood showed a red-cell count of 3,650,000, with 10.7 gm. of hemoglobin. The white-cell count was 8700, with 85 per cent neutrophils. A blood Hinton test was negative. The urine was acid, with a specific gravity of 1.018 and a ++ test for albumin. There were 50 white cells per high-power field in the sediment. The blood sugar was 65 mg. per 100 cc., and the nonprotein nitrogen 16 mg. The serum bilirubin was 0.9 mg. per 100 cc. direct, and 2.0 mg. indirect. The stools gave a ++++ guaiac test. One vomitus was guaiac negative.

X-ray films of the chest showed general enlargement of the heart. The vascular markings and hilar shadows were increased in diameter. The diaphragm was normal in position and showed limitation of motion. No definite evidence of fluid was seen. There was thickening of the interlobar septums between the right middle, upper and lower lobes. A plain film of the abdomen showed an area of calcification in the left side of the pelvis, probably a calcified fibroid. There was ascites, and the liver was slightly enlarged. No definite masses were seen. The splenic shadow was not well visualized. A barium enema revealed no evidence of gross obstruction. The examination was unsatisfactory because the colon had not been previously prepared. An electrocardiogram showed occasional ventricular premature beats. The rate was 110. There was slight late inversion of the T wave in Leads 1 and 2, and slight late inversion of the T wave in CF₅. The R wave was small in CF₂ and CF₄. The premature beats in CF₅ varied in direction.

The vomiting and pain continued, and one vomitus was guaiac positive. On the seventh hospital day the temperature rose to 103°F., the pulse to 140, and the respirations to 35. There were bronchial breathing and egophony, with dullness over the right base. The white-cell count was 28,500, with 90 per cent neutrophils. An x-ray film of the chest showed suggestive mottling of the right base. A throat culture gave few beta-hemolytic streptococci. The patient was given 1500 cc. of intravenous fluid almost daily, and 2.5 gm. of sodium sulfadiazine daily for six days. The stools still gave a ++++ guaiac test. An abdominal paracentesis on the eighth day yielded 4500 cc. of murky, red-brown fluid, with a specific gravity of 1.010. The cell count was 8800 red cells and 1200 white cells, 95 per cent of the latter being neutrophils. No tumor cells were seen. The fluid was not cultured. Abdominal examination revealed a tender right-sided mass extending to the right lower quadrant. A sense of resistance was palpated in the left upper quadrant, but there were no masses. A Miller-Abbott tube was passed with some relief.

On the seventh hospital day the temperature fell to normal, the pulse to 110, and the respirations to 30. The Miller-Abbott tube was three fourths of the way down, and although a few coils were seen in the stomach, the tip of the tube was in the small intestine. A few dilated loops of small intestine could be seen by x-ray, some of which appeared to be proximal to the tip of the tube. The patient continued to bring up bile and gastric contents by mouth. She was given 500 cc. of blood. A peritoneoscopy on the twelfth day revealed a mass in the right abdomen that looked like dilated loops of small bowel. These seemed to be adherent to the peritoneum of the abdominal wall. No evidence of carcinoma was seen. The following day there was icterus of the skin and scleras. The urine gave a ++ bile test. The chest was entirely clear both by examination and x-ray. Sulfadiazine was stopped. The distention continued, and the upper abdominal pain persisted. The white-cell count was 25,000. The van den Bergh was 3.3 mg. direct, and 4.1 mg. indirect. X-ray examination on the fifteenth hospital day showed the tip of the Miller-Abbott tube to be in the jejunum. There were several dilated loops of small bowel. A peculiar shadow of increased density was seen along the lateral margin of the right side of the abdomen, apparently between the bowel and the lateral abdominal wall; this suggested the presence of free air within the abdomen. There was evidence of fluid in the peritoneal cavity.

On the sixteenth day an exploratory laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: I wonder if you know how little the statement concerning the electro-

phragm is high on both sides in all the films, even in those taken previously. There was no marked change in the position of the diaphragm over a period of a month; if she was accumulating fluid in the abdomen, however, the diaphragm should have become progressively higher. The heart shadow is horizontal in the chest, because of the high position of the diaphragm, and appears somewhat larger than it actually is. There is no question about the heart's being enlarged. The enlargement is somewhat general but is greatest toward the left in the region of the ventricle. There is no marked dilatation or deformity of the great vessels, and no evidence of calcification. The calcified gland near the hilum probably represents tuberculous infection at some time.

The barium enema is shown here, and to its appearance is normal. There is no evidence of disease in the colon.

In this plain film taken of the abdomen, there are loops that contain air and some of them are small bowel. I think it is fair to say that they are slightly larger than those that we usually see. There is also a general haziness of the whole abdomen, often seen when there is a considerable amount of fluid. The progress of the Miller-Abbott tube was apparent rather slow. That occurs sometimes when the bowel is partially paralyzed. Whether it was due to that or to poor technic, I do not know. The large amount of gas that you see here is probably in the stomach. Again, there are moderately dilated loops of small bowel. It does not seem as if the obstruction in the small bowel as shown in these films is sufficient to have caused the patient's symptoms. It is not very striking evidence at any rate. About the size of the liver — there was, of course, a rather high diaphragm, and the lower edge of the liver is not well

these two things, as well as a positive guaiac test on the stools. I shall dispose of certain things without hesitation.

Any free air in the peritoneal cavity was probably the result of the peritoneoscopy. The patient had a definite increase in indirect bilirubin, and I suspect that this had something to do with the bloody fluid in the peritoneal cavity. I must, then, co-ordinate a positive indirect bilirubin and heart disease of some kind with the mass in the right upper quadrant, the bloody fluid in the peritoneal cavity and the positive guaiac test in the stools, and I am not finding this too easy. If she had not had bloody fluid, I could make a diagnosis that would satisfy me even though it might be wrong. With this combination I can make a diagnosis that is wrong but cannot have the pleasure of making one that completely satisfies me.

The first diagnosis that should be considered is cancer. The patient was forty-six years old and had ascites, bloody fluid in the peritoneal cavity, a mass in the right upper quadrant and a mass in the pelvis. Carcinomatosis is a logical diagnosis and I cannot talk myself out of it except on one basis. Bloody fluid in the peritoneal cavity due to cancer is usually associated with a lot of excrescences and with fairly obvious carcinomatosis as seen either through the peritoneoscope or at exploration. It is my impression that it most commonly comes from ovarian carcinoma and that large tumor masses usually sprout out here and there in the peritoneal cavity. If peritoneoscopy did not reveal any of these things, then I cannot make that diagnosis.

How about carcinoma of the bowel? The positive guaiac test in the stools, the mass in the right upper quadrant, the secondary anemia and the bloody fluid are suggestive. I cannot, however, make a diagnosis of carcinoma of the bowel and be satisfied. I do not recall that I have seen bloody fluid in the peritoneal fluid secondary to intestinal cancer. I am sure one can get it but there again, I have the same problem of the peritoneoscopy, and I have to drop it.

I might make a diagnosis of a gallstone that has eroded through the gall bladder to form an abscess, but I have to drop that diagnosis immediately because of the bloody fluid. That is definitely out so far as logical reasoning or any experience of mine goes.

I might make a diagnosis of acute pancreatitis, which can cause bloody fluid and make a person quite sick, but this story is too chronic. When pancreatitis causes bloody fluid, one has a fairly acute, dramatic process. This woman did not present that picture, so I must drop that diagnosis.

What else causes bloody fluid and a mass? Torsion of an abdominal viscus will do it, as will some interference with blood supply to a segment of bowel, either due to mesenteric emboli or mesenteric thrombosis. Strangulation of the small bowel and

obstruction will give bloody fluid and a mass. Here again, I cannot happily make a diagnosis of strangulated small-bowel obstruction for two reasons: I do not believe she had an obstruction, and obstruction due to strangulation should have a sudden, acute onset. This type of obstruction may go over into a chronic state, with a mass and abscess with dead bowel that is walled off, but it should have a sudden onset. There is no dramatic onset here that I can pick out.

What about mesenteric thrombosis? Recurrent emboli or thrombi ultimately culminating in death of a segment of bowel with localization and walling off of this dead bowel is entirely within the realm of possibility. The presence of heart disease is quite in keeping with this interpretation. This would also give a positive guaiac test in the stools, but is again a farfetched explanation it seems to me; yet I know it occurs. It is so uncommon, however, that it is a difficult diagnosis to make.

I have almost talked myself out of all the things that I can think of, without arriving at a positive conclusion. I think that this woman had a process in the right upper quadrant that involved the bowel, probably the small bowel. I suspect that there was a perforation and localized walling off of that bowel. If I say that and if I believe that that is what she had, then I have to explain it on the basis either of some fairly unusual manifestation of recurrent torsion ultimately ending in strangulation or of many small, minor insults to this woman's vascular tree ultimately ending in one of sufficient magnitude to cause death to at least a small segment of bowel with a resulting localization around it. She may have had general peritonitis, but there is no reason to suppose that she did. She did not at the time of peritoneoscopy. I do not believe that she had mechanical small-bowel obstruction. I cannot do any better than that.

DR. BENJAMIN CASTLEMAN: Dr. Williams, would you like to comment?

DR. CONGER WILLIAMS: I saw this patient when she first came in. She did not speak English, and we could not obtain a history. I thought, as Dr. McKittrick did, that she had some sort of heart disease, but I did not know what. There was definite evidence that she had congestive failure. There was an inconstant gallop rhythm, a very loud pulmonic second sound, pulmonary congestion, dilated neck veins and peripheral edema. I believed that the peripheral edema might have been due in part to a low serum protein, but it turned out later on that the serum protein was not quite low enough to account for the edema and that she did have several other things pointing to heart failure. So far as etiology is concerned, the only thing that seemed reasonable was hypertension, which was moderate — 150 systolic, 100 diastolic — when she came in, with some indication that it might have been higher in the past. We discovered later that

she had had asthma for some time. But I still thought that the diagnosis of chronic cor pulmonale was unlikely. For one thing, the asthma was not severe enough or of long enough duration to produce it. Also the electrocardiographic findings, which are usually important in making that diagnosis, pointed to involvement of the left rather than of the right ventricle.

She responded to diuretic therapy. I did not see her after the first four days.

DR. MCKITTRICK: I feel prouder of my diagnostic acumen as a cardiologist than as a surgeon at this point.

DR. PAUL ZAMECNIK: Retroperitoneal sarcoma can be silent outside the bowel and produce bloody ascites. It is not likely to produce a ++++ guaiac test, however.

DR. MCKITTRICK: Do you think it could produce bloody ascites without involvement of the peritoneum?

DR. ZAMECNIK: It might be difficult to see a retroperitoneal growth by peritoneoscopy, but it could produce ascites.

DR. REED HARWOOD: One gets bloody ascites with thrombosis of the portal vein, probably secondary to liver metastasis.

DR. CASTLEMAN: I shall read part of the operative note:

There was some free fluid in the abdominal cavity, and the small bowel was densely adherent. One loop of small bowel, estimated to be 60 to 75 cm. long, was completely covered with fibrin. There were small abscesses found between the leaves of the mesentery. The biliary tree seemed entirely normal. After the septic area had been opened up, the wound was closed without drainage.

It was impossible to say what was the cause of the sepsis. The right lower quadrant appeared completely free, although the appendix was not visualized. No diagnosis was made. It was thought that mesenteric thrombosis with partial healing could have produced this picture.

Would you like to say anything more at this point, Dr. McKittrick?

DR. MCKITTRICK: The only thing that I can say is that I still do not know what the diagnosis was. But I am sure of one thing, — and Dr. Castleman will bear me out, — multiple small emboli or thrombi in the mesenteric vessels sometimes do not result at once in bowel necrosis; so that the long history does not exclude this diagnosis. I am still intrigued with the bloody fluid. As to what it was, I have no further comment.

CLINICAL DIAGNOSIS

Carcinoma?
Lymphoma?

DR. MCKITTRICK'S DIAGNOSIS

Local gangrene of small bowel with abscess, probably secondary to thrombotic or embolic occlusion of vessels of mesentery.

ANATOMICAL DIAGNOSES

Mesenteric embolism (arterial).
Infarction of small intestine.
Cardiac hypertrophy and dilatation (? hypertensive type or idiopathic congenital).
Mural thrombi: left ventricle.
Thrombosis of mesenteric and portal veins.
Pulmonary infarcts.
Jaundice.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed that this mass was gangrenous, matted together, small bowel, which had resulted from mesenteric arterial embolism. There was also venous thrombosis, which was probably secondary to the arterial thrombosis. The source of the emboli was the left ventricular cavity. The heart was moderately enlarged. We could find no evidence of intrinsic heart disease except that there were numerous thrombi attached to the left ventricular wall in among the trabeculae carneae without underlying infarction, an extremely unusual condition. Ordinarily one sees them in the auricles in a patient with heart failure and fibrillation. To find them in the ventricle without myocardial disease is extremely unusual, but they were without question the source of the mesenteric emboli. There was also an extension of the mesenteric venous thrombosis into the portal vein, and many of the radicles of the portal vein throughout the liver contained thrombi. That in itself was not sufficiently extensive to be the cause of the jaundice, but there were numerous infarcts in the lung, and certainly the combination of infarction of the lungs and liver disease was enough to produce jaundice.

I am still intrigued with the type of heart disease. The coronary arteries were perfectly normal. The cardiac enlargement was probably on a hypertensive basis, but I cannot be sure. The left ventricular wall was moderately hypertrophied but the main cause of the enlargement seemed to be dilatation. The right side was not hypertrophied. I do not believe that it was caused by the repeated attacks of asthma.

DR. WILLIAMS: What did the myocardium show?

DR. CASTLEMAN: It was normal. There was no underlying infection or infarction.

The thrombi were not particularly adherent to the wall, and I wonder whether the treatment that she got for the heart failure — the digitalis and quinidine — might have produced mural thrombi. Does that ever occur?

DR. WILLIAMS: It is difficult to say. It has never been reported, to my knowledge. The reason I asked about the microscopic picture is that in Fiedler's (or "isolated") myocarditis¹ such mural thrombi have been reported as a frequent complication.

DR. CASTLEMAN: There was no evidence of myocarditis. The only other possibility is idiopathic

congenital hypertrophy of the heart in adults, such as the cases reported by Levy.² In these cases there are ventricular thrombi, but in his cases and the two that we have had the heart was enlarged to 600 or 700 gm. Here it weighed about 400 gm.

DR. WILLIAMS: Was the ventricular wall thickened?

DR. CASTLEMAN: Slightly.

CASE 30112

PRESENTATION OF CASE

First admission. A forty-five-year-old married social worker entered the hospital because of pain in the back.

Six years before entry she had had an attack of vague gastrointestinal symptoms, with epigastric discomfort and gas. Three years later she had had recurrence of the symptoms as well as occasional sour regurgitations and vomiting. She gradually improved and became essentially well until eighteen months before entry, when she developed pain low in the back and felt extremely tired. She lost about 24 pounds in two or three months. Three months before admission she had had a recurrence of the pain in the back and had also developed epigastric pain. She had had the menopause at the age of thirty-eight.

Physical examination showed a well-developed, well-nourished woman. The heart and lungs were normal. There was marked tenderness without spasm or masses in the left upper quadrant. Examination of the spine was negative, as were the pelvic and rectal examinations.

The blood pressure was 110 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,440,000, with 13.6 gm. of hemoglobin. The white-cell count was 9300, with 57 per cent neutrophils. The urine was negative. The stools gave a ++++ guaiac test.

X-ray examination of the lumbar spine and pelvis showed only some new-bone formation about the lateral margins of the right sacroiliac joint. A gastrointestinal series showed, on the lesser curvature just distal to the angle of the stomach, a 2.5-cm. irregular crater with considerable peripheral swelling.

On the thirty-sixth hospital day a subtotal gastrectomy was done. The pathological diagnosis was colloid carcinoma, with metastases to the regional lymph nodes. Postoperatively there was some pain in the abdomen and back, but this disappeared and she was discharged on the fourteenth hospital day.

Second admission (one year later). Following discharge she had had considerable morning nausea and lack of appetite but had carried on until three days before admission, when she developed persistent pain in the left lower quadrant that radiated to the left side of the back. On the day of admission she vomited once. The bowel movements had not been altered.

Physical examination revealed tenderness in the left quadrant. The pelvis showed marked tenderness on motion of the cervix and in the posterior cul-de-sac and a 2-cm. hard tender mass in the right vault. There was considerable vaginal discharge.

The pulse, respirations and temperature were normal.

The white-cell count was 11,100. The urine showed a + test for acetone, a + test for albumin, and the sediment contained occasional red cells and white cells.

X-ray films of the abdomen and chest were negative. No bone metastases could be seen. An intravenous pyelogram was essentially negative. A vaginal smear showed many *Trichomonas vaginalis*.

The patient's condition improved considerably, and she was discharged on the fourth day.

Third admission (twenty-one days later). Following discharge she had continued to vomit three or four times daily. The vomitus consisted of bile-stained fluid without solid material. She had had some diarrhea. Four days before admission she had an episode of vaginal bleeding. She passed several clots for the next three days and then stopped spontaneously. There was no pain or cramps.

Physical examination showed a thin cachectic woman in no distress. There was moderate tenderness to deep palpation in the entire left abdomen. Pelvic examination showed a normal cervix, a very small uterus and a large round, solid, somewhat fixed, but movable mass in the right vault.

The temperature, pulse and respirations were normal. The blood pressure was 122 systolic, 80 diastolic.

The red-cell count was 3,510,000, with 80 per cent hemoglobin. The white-cell count was 8000, with 56 per cent neutrophils. The urine was essentially negative.

A gastrointestinal series, x-ray films of the chest and intravenous pyelograms were negative.

An operation was performed on the sixth day.

DIFFERENTIAL DIAGNOSIS

DR. GORDON A. DONALDSON: Throughout the course of this case history there is one complaint that persisted — pain in the lower part of the back, which continued as such for one and a half years. For the month previous to the final episode it was more marked on the left side and was associated with left lower abdominal pain and tenderness. This latter type of pain suggests disease in the pelvis.

At first, when I read the abstract, the colloid carcinoma of the stomach appeared to be a red her-

ring. She gave a perfectly typical history for carcinoma of the stomach: she had had vague gastrointestinal symptoms and epigastric discomfort for six years; she had gradually developed epigastric pain, regurgitation and vomiting; and she had lost 24 pounds in weight. There was, however, little anemia, indicating that the carcinoma was probably an early one. She did come to operation and had a subtotal gastrectomy with an uneventful convales-

ing she was able to swallow barium for a gastrointestinal series, which showed a normal upper intestinal tract. Moreover, the genitourinary tract was normal by x-ray. So we have a rapidly growing mass in the right pelvis and pain in the left side.

I wonder if we could see the last gastrointestinal series. Does it help?

DR. LAURENCE L. ROBBINS: No; it does not show the mass particularly well, and most of the films

FIGURE 1. Photomicrograph of the Krukenberg Tumor.

cence. The regional lymph nodes, surprisingly enough, were found to contain cancer.

Another feature that we note about the first admission is that they were interested in the lumbar spine and pelvis and found that, by x-ray, she did have changes about the sacroiliac joint on the right side. This would help to explain the pain in the back for the previous one and a half years. We must therefore keep in mind the facts that she had a definite pathological diagnosis of colloid carcinoma in the upper abdomen and that she had x-ray changes in the pelvis.

That takes us up to the second and third admissions, at which time attention was directed to the lower abdomen and pelvis. Her pain had changed, being more intense on the left side. She also had a mass on the right side of the pelvis and bleeding. Painless bleeding associated with clots of four days' duration in a woman who is seven years after the menopause is quite significant. I do not believe that the mass was in the gastrointestinal tract, nor do I believe that she had diverticulitis of the sigmoid, since she had no elevation of the white-cell count, temperature or pulse. In spite of the vomit-

ing of the gastric anastomosis and not in the region of the mass.

DR. DONALDSON: I should like to blame all the trouble at the last admission on the mass in the right side of the pelvis. The uterus was described as extremely small—a postmenopausal uterus. So I doubt whether there was anything in the uterus that initiated the bleeding. In addition, the ovaries were normal. This mass could have been the fallopian tube; in which case it must have had a tumor. Carcinoma of the tube may cause bleeding, but usually consists of occasional spotting. Such a tumor is rare and is extremely unlikely in this case.

So we come down to the fact that the right ovary was pathologic, and again I do not believe there was any inflammation in the ovary because of the clinical picture. In fact the whole picture fits much better with carcinoma. The patient had anemia and was cachectic. What sort of tumor could this have been? A granulosa-cell tumor could cause her bleeding, but it is usually not massive for four days, and the patient had none of the secondary changes that one generally associates with a granulosa-cell tumor. Also the tumor grew quickly.

rapidly, — a matter of three weeks, — so I rule that out.

Another possibility is a Krukenberg tumor. The patient had a colloid carcinoma of the stomach, the cells of which are histologically similar to those that Krukenberg described, and I think this might well fill the bill. The left-sided pain and fullness in the cul-de-sac could be disease in the other ovary, which was not definitely palpable. Krukenberg tumors are often bilateral. It may not be necessary to say just what sort of tumor this was; but I believe it was a carcinoma of the right ovary, for which operation was undertaken.

DR. JOE V. MEIGS: Our reasoning was similar to that of Dr. Donaldson. When I examined the patient, I was not at all sure that the mass was one-sided. It moved freely with the uterus, and most of us thought that it was connected with the uterus. We had a difficult time explaining why the patient bled. We brought up the possibility of a Krukenberg tumor and advised that she be peritoneoscoped. At peritoneoscopy Dr. Benedict thought that the tumor was a fibroid.

CLINICAL DIAGNOSIS

Fibroid uterus.

DR. DONALDSON'S DIAGNOSIS

Krukenberg tumor of ovary.

ANATOMICAL DIAGNOSIS

Krukenberg tumor of ovaries.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The specimen that we received included a small uterus, almost small enough to be called an infantile uterus, and two large masses, one on the right side, measuring 9 cm.,

and one on the left, measuring 5 cm. The surface of the tumors was smooth and moderately firm. On section the masses showed a firm, smooth, sarcomatous appearance, which is the classic picture of the Krukenberg tumor. In fact when the tumor was first described by Krukenberg* it was thought to be a sarcoma rather than a carcinoma. Microscopic examination showed a signet-ring type of carcinoma (Fig. 1). The uterus had a hyperplastic endometrium, which may have been the cause of the bleeding. We later found out that a vaginal smear showed an estrogen effect, which brought up the possibility, before we knew that there was endometrial hyperplasia, whether such a carcinoma can produce an estrogen effect.

DR. MEIGS: In my investigations of ovarian tumors in women past the menopause I have found that any type of tumor may be accompanied by uterine bleeding. Why, I do not know.

DR. ARTHUR HERTIG: If the stroma of the tumor was involved, it might have produced an estrogen effect. It is a far cry, but it may be analogous to the estrogenic quality of the ovary. I never believed that Krukenberg tumors put out estrogen. Perhaps they do.

DR. MEIGS: I looked carefully and found no evidence of follicle cyst. I have seen Krukenberg tumors that had cysts with perfectly good epithelium, which might secrete estrin.

DR. CASTLEMAN: We did not find any cysts. I do not know why she had endometrial hyperplasia, but that was probably the direct cause of the bleeding.

DR. MAURICE FREMONT-SMITH: The vaginal smear showed *Tr. vaginalis*, which sometimes gives the appearance of an estrogen effect in the vaginal smear.

EPIDEMIC STARVATION

THE countries of occupied Europe are faced with potential postwar problems that run the entire gamut of political, economic and social questions of the most vital import. None will be more fundamental or more pressing than those dealing with the nutritional status of liberated populations. In any war, starvation has invariably accompanied prolonged hostilities; conquest and occupation have always caused suffering and want. Mass starvation has rarely, if ever, been distributed so ruthlessly or so systematically to civilian populations as has been the case in occupied Europe in the present struggle. The will to resist has been directly attacked in this total war by all the means possessed

by a force that is purposeful and entirely with conscience. In concentration camps measures have been most systematically carried with results that, for the most part, are still matter of conjecture rather than of carefully documented and exact knowledge. Prolongation of hostilities in Europe through another six to twelve months exaggerate to an unprecedented degree the process of attrition that have been initiated in concentration camps and among civilian population in occupied areas. Reconstruction problems among exhausted survivors will tax to the full the resources of the United Nations if a restoration of health and morale is to be obtained for the victims of tyranny. To what extent mass malnutrition affects postwar thinking on the Continent can hardly be estimated. Since it is certain that chronic nutritional deficiency is not conducive to normal intellectual performance, adequate and carefully planned feeding of European sufferers must be a matter of stern necessity.

The clinical aspects of epidemic starvation are clearly described in the report from southern France published elsewhere in this issue of the *Journal*. The specific manifestations of extreme avitaminosis, protein starvation, lack of hematopoietic factors and insufficient caloric intake, with the modifying effects of intercurrent infection, are graphically presented. Both from the humanitarian and scientific points of view the article is of immediate current interest and should be carefully scrutinized.

RELIGION AND PSYCHIATRY

THE question of the relation, if any, between psychiatry and religion is now and again proposed by someone of speculative mind. The proposal of such a question might be considered a compliment to the "mental sciences" or it might be looked upon as an attack on the body of knowledge that professes to have insight into the deepest, basic motives of human activity.

Religious belief of some kind or other is as old as human nature and antedates the earliest beginnings of scientific inquiry. Psychiatry is a fairly recent member of the scientific family. Does this

psychiatry, dare or insist on classifying the tendency toward religious belief as founded in phantasy, delusion, wishful thinking? Is religion what Karl Marx called it, "the opium of the people"?

Most psychiatrists are familiar with the criticism that their branch of medicine analyzes its patients' problems, points out weaknesses and frailties and concludes with unhelpful advice comparable to "Now it's up to you." This process supposedly leaves the patient with nothing to stand on or build upon and he must look in other fields if he is to find substantial help in his suffering. It is doubtful that such uninspiring and barren therapy is practiced frequently, and certainly the goal and standards of the best psychotherapy are constructive, not analytic alone. Therapy in psychiatry, as in all of medicine, should include an understanding of the part as well as of the science.

The propounder of the original question may say that this is well enough; perhaps psychotherapy does mean to be constructive, even though he knows of cases in which it was not, but he wants to get down to brass tacks, so to speak, and asks searching if psychiatry believes in and accepts the existence of a supreme or supernatural being, God, and in its therapeutic attempts uses this belief or concept in such manner that its patients learn that belief and faith in this existence are essential to their cure.

It may be assumed that they who do have a firm belief in the reality of an infinite being think that such faith is good. They do not berate themselves for having it and they are inclined to think that others would benefit in having the same conviction. They also would say that such trust is not selfish; that, on the contrary, it tends to make them more mindful of others. It is not compatible with religious belief for a person to be thankful that he, anyway, has his salvation whatever happens to the hindmost. The really religious person is concerned about and wants to help others.

Anyone knows, to use that surprisingly inclusive phrase, that being primarily interested in getting the biggest piece of cake for oneself is not good, far-sighted or wise. Psychiatry has found and has taught for years that in so far as the patient's troubles or maladjustments are not due to innate

or organic abnormalities they are dependent on the formative experiences of the early years of life. How a person meets this or that crisis or strain has a direct relation to what he has learned about self-control: to what extent he has gained the perspective which enables him to understand that his egotistic desires and needs may be of minimal importance in a vast universe of time and space.

Psychiatry has always known and taught that having and acting on the knowledge that there is something more important than the self makes for mental health. Geniuses, in varying degrees, may be exceptions, in that their egotistic desires may, in the long run, benefit others enough and more than enough to compensate for the headaches given their immediate associates by their personal idiosyncrasies and selfishnesses.

If good deeds, spontaneously performed, not done because Dale Carnegie says it works, plus a humility that finds others' accomplishments as stimulating, or nearly so, as one's own, plus a perspective out of which comes graceful acceptance of one's own frustrations, plus the conviction that one should do one's job well, whether or not one knows just why — if these sum up to religion, then psychiatry and religion are going in the same direction. If the questioner insists on absolute belief in God as a personality, there may be variance.

There is nothing to indicate that the psychiatrist who does not believe in God does not help his patients. There is nothing to indicate that the psychiatrist who believes in God is a better helper of his patients. Too frequently such a belief is rooted in egotism that cannot face the idea of a universe's going on with one's personal identity gone. It may be remembered, too, that preaching and argument are not always effective. Unostentatious example may carry farther. The old horse-water-drink problem is relevant.

Psychiatry, in therapy, does not want to take away from people their trust in God. It would prefer that they have it or that they achieve it if it can help them. To tell patients, however, that they must have such trust before they can be cured, or to base therapy on such prejudice, even though it might not be expressed in so many words, would be as uncharitable, and often as unprofitable, as

insisting on religious conversion before allowing drink or food to a starving man.

We are at one with God if we are more interested in the welfare of others than we are in personal needs, if the latter are of a kind from which nothing emanates except increased need.

MEDICAL EPONYM

WERNICKE'S DISEASE

The original account of this condition, by Carl W. Wernicke (1848-1905), at that time *Privat-dozent* at the University of Berlin, appears in his *Lehrbuch der Gehirnkrankheiten für Aerzte und Studierende* (Kassel and Berlin, 1881: Vol. II, pages 229 to 242), under the title "Die acute, hämorrhagische Poliencephalitis superior [Acute Hemorrhagic Superior Polioencephalitis]." A portion of the translation follows:

We are here dealing with an independent inflammatory, acute disease of the nuclei of the nerves supplying the eye muscles, which results in death within a period of ten to fourteen days. The localizing symptoms consist in associated ocular muscle palsies, which appear suddenly, progress and lead finally to almost complete paralysis of the eye muscles. Certain muscles, however, such as the sphincter iridis or the levator palpebrarum, are spared. The patients' gait becomes uncertain, showing a combination of stiffness with ataxia, usually suggesting the ataxia of the alcoholic. The general symptoms are striking, and consist in disturbances of consciousness, either somnolence from the outset, or an end stage of somnolence introduced by a more prolonged period of agitation. Further, in all 3 cases there was involvement of the optic nerve, consisting of inflammatory changes in the papilla.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BRADY — William F. Brady, M.D., formerly of Holyoke, died February 28 at his home in St. Petersburg, Florida. He was in his fifty-ninth year.

Dr. Brady received his degree from Tufts College Medical School in 1909. He interned at the Boston City Hospital and at the Providence Hospital, later studying abroad at the University of Vienna. He was elected to the American College of Surgeons in 1937. He was a member of the Massachusetts Medical Society, the American Medical Association and the Holyoke Medical Association.

His widow, his mother and a sister survive.

HOWARD — Margaret E. P. Howard, M.D., of Reading, died March 1. She was in her eighty-fifth year.

Dr. Howard received her degree from the University of Michigan Medical School in 1882. She was a member of the Massachusetts Medical Society and the American Medical Association.

A son and two grandchildren survive.

PALMER — Anna C. Palmer, M.D., of Milton, died February 10. She was in her eighty-seventh year.

Dr. Palmer received her degree from Boston University School of Medicine in 1888. She was president of the Cured Cancer Club and a member of the Massachusetts Medical Society and the American Medical Association.

COMMENT

Thirteen diseases exceeded the seven-year median du February. Three of these call for special mention: diphtheria meningococcal meningitis and scarlet fever.

Diphtheria has been commented on before. The increase that has been taking place the last few months must be laid, at least in part, at the door of laxness in immunization. Meningococcal meningitis this month reached the poor 61 cases — more than seven times the seven-year median. There was, however, a sizable drop from January's 94 cases. Scarlet fever is following the usual seasonal pattern but at a lower level than that of last year. It is, nevertheless, above the level of the seven-year median.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASE

Actinomyces was reported from: Fall River, 1; Devens, 1; total, 2.

Anthrax was reported from: Franklin, 1; Peabody, 1; total, 2.

Diphtheria was reported from: Arlington, 1; Boston, 2; Lawrence, 10; Melrose, 3; Somerville, 4; total, 21.

Dysentery, bacillary, was reported from: Beverly, 1; Boston, 2; Worcester, 9; total, 12.

Encephalitis, infectious, was reported from: Holyoke, 1; total, 2.

Hookworm was reported from: Edgartown, 1; total, 1. Malaria was reported from: Amesbury, 1; Amherst, 1; Boston, 1; Camp Edwards, 3; Cushing General Hospital, 4; Fort Banks, 13; Fort Devens, 25; Gardner, 1; total, 50.

Meningitis, meningococcal, was reported from: Barnstable, 2; Boston, 12; Brockton, 1; Cambridge, 1; Camp Edwards, 4; Easton, 1; Everett, 1; Fall River, 1; Fitchburg, 1; Banks, 1; Lawrence, 1; Lowell, 5; Lynn, 2; Malden, 3; Montague, 1; Newton, 1; Quincy, 1; Revere, 1; Sharon, 1; Somerville, 2; Southbridge, 1; Springfield, 1; Swampscott, 1; Wakefield, 1; Waltham, 1; Ware, 1; Westfield, 1; Westfield, 1; Winchester, 1; Worcester, 1; total, 61.

Meningitis, Pfeiffer-bacillus, was reported from: Boston, 1; Needham, 1; total, 2.

Meningitis, pneumococcal, was reported from: Billerica, 1; Boston, 1; Lawrence, 1; Sutton, 1; Springfield, 1; total, 4.

Meningitis, streptococcal, was reported from: Beverly, 1; total, 1.

Meningitis, other forms, was reported from: Boston, 1; Cambridge, 1; Gloucester, 2; Lynn, 1; total, 7.

Meningitis, undetermined, was reported from Attleboro, 1, Cambridge, 1, Everett, 1, Quincy, 2, Springfield, 1, total, 6 Salmoeila infection was reported from Newton, 1, total, 1 Septic sore throat was reported from Boston, 10, Camp Edwards, 2, Cushing General Hospital, 1, Lowell, 1, Lynn, 3, Marion, 1, Medford, 1, North Adams, 1, Quincy, 1, Revere, 1, Williamstown, 1, total, 23

Tetanus was reported from Lawrence, 1, total 1

Trachoma was reported from Boston, 1, West Newbury, 1, total, 2

Trichinosis was reported from Boston, 1, Medfield, 1, total, 2

Typhoid fever was reported from Beverly, 1, West Brookfield, 1, total, 2

Undulant fever was reported from Oxford, 1, total, 1

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT SERVICE

MONEY AID FOR RELOCATIONS

The Washington office of the Procurement and Assignment Service has recently announced that Congress has authorized a fund of \$200,000, to be administered by the United States Public Health Service, for the relocation of physicians and dentists. Payments of \$250 a month for three months as well as the costs of transportation, will be paid to physicians and dentists who desire to relocate, and the officials of the Public Health Service will work in close co operation with state medical and dental chairmen

MISCELLANY

TUBERCULOSIS AMONG VETERANS

Our national experience with tuberculous veterans of the last war has been unfortunate. Sadder still would be a repetition involving the men and women fighting World War II. The following paper (Dublin, L. J. Function of health officer in control of tuberculosis among veterans. *Am J Pub Health* 33 1425-1429, 1943) addressed originally to health officers, challenges every physician whose practice embraces a tuberculous veteran or the family of one.

During World War I inductions, knowledge and facilities for diagnosis were insufficient to screen out many men suffering from tuberculosis, particularly presymptomatic disease. Thus many active cases entered the Army. Hardships of training and combat produced still more. After the war, care of tuberculous veterans fell to the newly organized Veterans' Bureau. Hospitals and sanatoriums were erected. The service became a major medical activity of the Bureau and of its successor the Veterans' Administration. As early as 1923, a total of 23,653 tuberculous veterans were admitted to treatment in one year. At first, care was limited to tuberculosis connected with military service. Subsequently, cases with disease unrelated to military service became eligible. As a result, tuberculosis admissions have continued numerous. During fiscal 1942, after almost a quarter century, hospital admissions numbered 9658. Over 300,000 such admissions and readmissions have accrued in hospitals of the Veterans' Administration or other government state and civil institutions since the last war.

The government has spared no efforts or funds in erecting and equipping modern hospitals and in providing adequate medical personnel. In March, 1942, there were 5217 beds to meet current needs embracing tuberculous veterans of the present war and including tuberculosis beds in veterans' psychiatric hospitals. Besides having all costs of hospitalization and transportation to hospitals paid, tuberculous veterans also receive compensation payments scaled from \$8 to \$100 per month, based on varying grades of dependency, and served pay.

tempted many to discontinue hospital care and attempt a cure at home. Standards of operation in veterans' hospitals are generous. In 1942, excluding overhead, the per diem cost of operation was \$4.37 per patient and the total direct costs of treatment

approached \$8,000,000. Compensation of World War I veterans with partial or total disability due to tuberculosis, whether or not service connected, amounted to approximately \$40,000,000 during that fiscal year. Such veterans then still numbered 63,000 and exceeded by many times the number accepting hospital care. Disability payments over the last twenty five years aggregate about \$1,000,000,000.

Despite the admirable services available to tuberculous veterans, the experience of their hospitals has been unfavorable. Thus in 1942, of the 9854 cases discharged from these hospitals, only 19 per cent were designated "arrested" at discharge with 0.3 per cent "apparently arrested" and 0.8 per cent "quiescent"—a bare total of 3 per cent medically rehabilitated. The remaining discharges included "condition improved" 32.7 per cent, "condition unimproved" 28.9 per cent, "dead" 19.5 per cent, and "condition not stated" 16.0 per cent. The vast majority were obviously not ready for release. So called "improved" cases represent predominantly patients with unstable lesions, a large proportion leaving the hospital without authorization or consent. Thus the Veterans' Administration itself classified the hospitalization of 58 per cent of the cases as "incomplete." These 1942 figures are rather typical, although somewhat worse than those of earlier years.

Exact comparisons among various sanatoriums regarding results of treatment on the basis of such crude figures are impossible particularly now when World War I veterans admitted are older men, usually with chronic disease. Of recent admissions, only 4 per cent were "incipient" cases, 22 per cent "moderately advanced," and 74 per cent "far advanced." Even so, there is a painful contrast between the results with veterans and those achieved in well managed state, municipal and private sanatoriums. In a 1933-1934 survey of tuberculous hospitals and sanatoriums in the United States by the American Medical Association, patients discharged with tuberculosis "arrested," "apparently arrested" or "quiescent" accounted for 29 per cent of all discharged. Among Michigan state sanatoriums from 1930 to 1934 discharges included 61 per cent in these three groups. At Mount McGregor Sanatorium of the Metropolitan Life Insurance Company, of males discharged between 1919 and 1936, and excluding incipient cases, 48 per cent were in comparable categories. Even for cases far advanced on admission, the proportion was 34 per cent.

This deplorable situation among tuberculous veterans has not developed from lack of desire to help the men. Every one concerned aimed at optimum care. The chief failure was by legislators and others interested in veteran welfare to appreciate fundamental conditions necessary for effective treatment. In part outside pressure was brought to bear to liberalize financial provisions. These measures actually have minimized effective control over the movement of the tuberculous Veterans not subject to ordinary hospital restrictions come and go almost at will regardless of their condition and against medical advice. Patients have been readmitted as many as twenty four different times. Six to eight admissions of the same man are common despite official effort to educate and persuade patients to complete their hospital care and measures to exclude offenders from immediate rehospitalization. Much of the discipline essential to success in treating tuberculosis is lacking. Indeed laws and practices have so evolved that it often financially benefits men to leave the hospital or avoid it altogether. This creates an impossible situation, undermining morale of veterans and professional staff alike.

More serious than mere failure to rehabilitate the patient, discharge before cure exacts its toll on the Nation. It has allowed thousands with communicable tuberculosis to return to civilian communities to live at home or travel about under little or no medical supervision. State and local health officers have assumed little responsibility for men traditionally regarded as wards of the federal government. Few patients have recovered, most have constituted an army of discouraged men spreading tuberculosis in their home communities.

Administration authorities and veterans' leaders are recognizing the need for a remedy, beginning with a drastic change in viewpoint. Specific improvements are being considered and necessary legislative measures will be debated. The American Legion is launching a campaign through its local branches to see that veterans resume and continue hospital treatment until discharged with medical approval.

What is to be done? First, new controls must render liberal benefits medically effective, preventing the drifting of tuberculous veterans until the disease is "arrested" or, at least, not a menace.

Second, the medical profession must co-operate with the Veterans' Administration in the follow-up of tuberculous ex-patients. The Administration has indicated that it will release information to state and local health officers, and routines for getting such reports are imperative. Men still in need of sanatorium care who will not stay in veterans' institutions should be hospitalized in state or local sanatoriums, with legal power invoked where necessary. Each man's circle of contacts should be thoroughly combed for additional cases.

Finally, a genuine effort must be made to protect the large crop of tuberculous veterans inevitable from the present war. It is likely that the Veterans' Administration will function under regulations and procedures governing the care of veterans of World War I. Already, many of the tuberculous veterans of the new war show the same restlessness and abandonment of hospital care that have produced calamitous results among the older men. With new cases already numerous, the stage may be set for another great medical tragedy. Lack of discipline and mistaken generosity may not only take their toll of young men who deserve to get well and resume useful lives, but may seriously delay control of tuberculosis in the general population — unless we act! — Reprinted from *Tuberculosis Abstracts* (March, 1944).

BOOK REVIEWS

Virus Diseases. By members of the Rockefeller Institute for Medical Research. 8°, cloth, 170 pp., with 11 illustrations and 2 plates. Ithaca, New York: Cornell University Press, 1943. \$2.00.

This book consists of six lectures that were delivered by members of the Rockefeller Institute for Medical Research at Cornell University in the spring of 1942. The titles of the lectures were as follows: "Virus Diseases, with Particular Reference to Vaccinia," by Dr. Thomas M. Rivers; "Chemical Structure and the Mutation of Viruses," by Wendell M. Stanley, Ph.D.; "New Hosts as a Key to Progress in Plant Virus Disease Research," by Louis O. Kunkel, Ph.D.; "Swine Influenza," by Dr. Richard E. Shope; "Human Influenza," by Dr. Frank L. Horsfall, Jr.; and "Viruses and Tumors," by Dr. Peyton Rous. Excellent bibliographies are appended to each lecture. An understanding of the contents of this volume is furnished by a quotation from the foreword:

Numerous papers regarding viruses have appeared in scientific journals. Many new virus diseases have been discovered in recent years. Virus workers are not always in agreement and the same virus worker not infrequently changes his notions. Thus, the realm of viruses and virus diseases reminds one of a boom town; nothing is settled. As a result of this confusion, few investigators have had the temerity to write books about viruses. Nevertheless, many facts about these peculiar agents have been established and are sufficiently interesting and important to warrant being brought together under one cover. In this set of Messenger Lectures, six virus workers have attempted to do this for the fields with which they are familiar.

Kaiser Wakes the Doctors. By Paul de Kruif, M.D. 8°, cloth, 158 pp. New York: Harcourt, Brace and Company, 1943. \$2.00.

Paul de Kruif is an enthusiast, and when one reads the writings of such he must be on his guard against being "taken in." There is a seed of truth in most of his writings, but all too often the seed is enlarged into a nonexistent tree.

In reading this book one must admit that the medical care given to the Kaiser employees is excellent. Dr. Garfield and his group have used the best of organized medical facilities to care for the sick and injured among the thousands of employees, the scheme being financed by a prepayment plan in which both employer and employee participate. It differs little from other prepayment plans already in operation, such

as the Endicott-Johnson, the Sante Fe and the Birmingham Coal. The factor of drama that enabled de Kruif to write a book is the sudden growth, which directly paralleled the mushrooming of the Kaiser plant.

This book is not an indictment of existing medical care in the United States. If anything it shows that American medicine under the system of individual initiative can formulate methods for meeting any emergency, and it is doubtful, at least to the reviewer, if any form of bureaucratic medicine could have handled the problem nearly so well as the present competitive system.

Paul de Kruif has read the final report of the Committee on the Costs of Medical Care, in which it is stated that prepayment and group practice are essential. But beyond this, and of greatest importance, is the recognition that the tactics must vary with the needs and facilities of the communities that are to be served. De Kruif has described one method, but in a vast country like the United States no single method will serve. Each small unit must build upon existing facilities to enlarge medical care, and when this is done it may result in a voluntary insurance scheme for covering the costs of medical care, in an industrial prepayment plan or even in direct government subsidy, but not one to the exclusion of all others.

Biochemistry of the Fatty Acids, and their Compounds, the Lipids. By W. R. Bloor. American Chemical Society Monograph Series. 8°, cloth, 387 pp. New York: Reinhold Publishing Corporation, 1943. \$6.00.

The scope of this authoritatively written monograph is best shown by a citation of its chapter titles: "Chemistry," "Digestion and Absorption," "Lipids of the Blood," "Lipids in the Tissue," "Lipid Metabolism" and "Lipids of Secretion and Excretion." The emphasis of the book is on the physiology rather than on the chemistry of the lipids, and it thus makes a valuable guide for those interested in the borderlands of chemical physiology and medicine. The chapter on absorption and the one on blood lipids are especially well conceived and presented.

Oral Diagnosis with Suggestions for Treatment. By Kurt H. Thoma, D.M.D. With contributions by Fred Trevor, D.M.D., Henry Goldman, D.M.D., and David Weisberger, D.M.D. Second edition, revised. 8°, cloth, 495 pp., with 666 illustrations, 63 of them in colors. Philadelphia and London: W. B. Saunders Company, 1943. \$6.75.

The second edition of this book has been revised and renamed, the original edition having been called *Oral Diagnosis and Treatment Planning*.

Additions include a new chapter on wounds and burns, elaboration of the chapter on fractures of the teeth and jaws, and chapters on environmental changes in the teeth and on diseases of partially and completely edentulous mouths, as well as contributions by Drs. Trevor, Goldman and Weisberger on dental caries, periodontal disease and the relation of constitutional disease to oral lesions.

The volume is profusely illustrated, many of the illustrations being unusually clear cut so that even the finer details of the lesions are observable.

The book covers diseases and abnormal conditions of the teeth, jaws and other organs and tissues of the mouth, with suggestions for treatment at the end of each chapter. The arrangement represents a useful and constructive departure from the usual textbook. The therapy both for local lesions and for constitutional and deficiency conditions is brought up to date and given in detail.

The volume is recommended primarily as a textbook for the dental student in the courses covering oral diagnosis or oral medicine, now considered so vital in dental education. As a reference book for the dental practitioner it should stimulate an interest in the relation of oral lesions to disease elsewhere in the body. The physician and medical student could well make use of this book, particularly since oral disease, with its related dental problems, is a neglected field in the medical curriculum.

THERAPY WITH FEMALE SEX HORMONES*

GEORGE VAN S. SMITH, M.D.†

BROOKLINE, MASSACHUSETTS

THIS paper is concerned for the most part with functional disorders, since it is almost exclusively in these that hormones are of value. The use of the term "functional" is an admission of ignorance concerning the actual cause and mechanism of a given disability. Irregularities of living — namely, faulty diet, insufficient rest, inadequate healthy activity, changes of environment, strained social relations, absence of healthful routines, shocking episodes, poor emotional adjustment, psychic disturbance, ill-suited occupation, bad habits and so forth — are often obviously, and apparently causally, associated with all sorts of functional disturbances of the various bodily systems for which no organic basis can be ascertained by available methods of study and diagnosis. It is therefore reasonable to assume that these irregularities of living may be more or less involved in the development of gynecologic functional disorders, and indeed careful inquiry often reveals that such is probably the case. Fortunately, many functional upsets are likely to be temporary because they either force the patient to mend her ways spontaneously or to consult some physician who points out her errors of living and the means of correcting them. With exceptions, prescribed and voluntary adjustments of living and constitutional changes over a period of time have more to do with curing patients than has the therapy administered specifically for the complaint. The therapy presumably tides the patient over and sets the stage for cure.

FUNCTIONAL DISORDERS OF MENSTRUATION

Before taking specific steps concerning the patient's presenting complaint, four things should be done. First, well-recognized causes of manifestations similar to those of functional origin must be ruled out. These include amenorrhea due to or associated with congenital anomalies; systemic infections; wasting disease; diabetes; hyperthyroidism;

ovarian, adrenal and pituitary tumors; Cushing's and Fröhlich's syndromes; Simmonds's disease and anorexia nervosa; dysmenorrhea due to pelvic inflammation; endometriosis, adenomyosis and tumors; abnormal genital bleeding due to pathologic pregnancy, cancer, polyps, tumors, inflammations, endometriosis or blood dyscrasias; and sterility due to inflammations, anomalies, endometriosis and tumors; and pathologic entities in the male. Second, the patient should be advised concerning better living habits — those of elimination, rest, activity and occupation — and the adjustment of social problems. Third, the proper medication, such as sedatives, iron and thyroid, should be recommended. Lastly, the elimination of focal infections should be seen to. Prescribing thyroid for patients with the disabilities outlined is more a matter of art than of science. The value of such treatment cannot be measured in terms of the basal metabolic rate and the blood cholesterol alone. Most of those who are studying and treating patients with pelvic symptoms and signs of dysfunction rely on it as a basic part of therapy and are convinced of its value, although it is impossible to explain the mechanism of its effect.

If menstruation does not begin before the age of sixteen, a diagnosis of *primary functional amenorrhea* should be considered, general examination and indicated studies performed, and general treatment begun, as outlined above. If no menstruation occurs by the age of eighteen, this diagnosis is reasonably certain, and efforts at specific treatment may be undertaken. That the amenorrhea is indeed functional can be determined only by demonstrating fundamentally normal genitalia. Without abdominal exploration the diagnosis remains presumptive. Performing an operation simply to prove that the cause is not absent or rudimentary ovaries is hardly warranted. Since there is no tangible benefit to the patient by operation, it seems better to assume that the amenorrhea is functional until the passage of time and the failure of treatment indicate otherwise. Primary and presumably functional amenorrhea is not associated with any other

*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 11, 1943.

†William H. Baker, Professor of Gynecology, Harvard Medical School, visiting surgeon and director of Peering Research Laboratory, Free Hospital for Women, Brookline, Massachusetts.

unequivocal stigmas of endocrine imbalance. It occurs in normal young women in whom uterine bleeding can be artificially induced.

Secondary or acquired functional amenorrhea, by definition, means that uterine bleeding has previously occurred. That it is not likely to be permanent is attested by the small number of patients seen with this complaint between the ages of thirty and forty. It is unassociated with any other clear stigmas of endocrine imbalance.

An immediate or possible future desire for pregnancy is the main reason for treating patients complaining only of amenorrhea, and in this group may be included those with delayed, skipped and scanty periods. Ovulation is the ultimate aim, although the psychologic value of induced simple bleeding may be great. Unfortunately, ovulation as an immediate result of available therapy cannot yet be promised, but with persistent treatment and the passage of time it may be reasonably expected.

The following treatment is suggested for patients with amenorrhea. Give 1 mg. of diethylstilbestrol orally daily with breakfast for thirty-five days, and 10 mg. of progesterone intramuscularly daily for the following five days. Two to five days after the last injection, a two-day to five-day flow will probably ensue. Counting the beginning of flow as the first day, give 0.5 mg. of diethylstilbestrol daily from the fourth through the twentieth day, and 10 mg. of progesterone intramuscularly daily from the twenty-first through the twenty-fifth day. A period will probably occur around the twenty-eighth day. Repeat the last two steps twice, and then again twice, but reduce the diethylstilbestrol to 0.3 mg. daily. After the next period, give the usual course of diethylstilbestrol daily but omit the progesterone. By that time a spontaneous flow may occur and recur at regular intervals on 0.3 mg. of diethylstilbestrol taken daily, except during flowing. If there is no flow by the thirtieth day, give the progesterone series again.

If after one or more trials with the above schedule of treatment no spontaneity of flow is discernible, it is reasonable to assume that the patient has some basic irremediable defect and that nothing further is to be gained. This therapy is worth trying in patients with Fröhlich's syndrome.

For patients with delayed, skipped or scanty periods, give the treatment described above for the fourth to the twenty-fifth day, and repeat it as seems desirable. So often do these patients have premenstrual distress or tension that this program will be found especially salutary.

Presumably because of variations in intestinal absorption, the orally active anhydro-hydroxyprogesterone cannot be counted on as an effective substitute for injected progesterone. Neither may chorionic, pituitary or pregnant-mare-serum gonadotropins be expected to give predictable results in the above conditions or in the disorders to be dis-

cussed below. Undesirable reactions frequently follow the injection of such preparations. Furthermore, the gonadotropins of animal origin are likely to become ineffective from inducing acquired immunity. The rationale of the above program of treatment is based on the fact that the ovarian steroids have retroactive effects on the anterior hypophysis and that administering them so as to induce cyclic flowing seems to regulate pituitary gonadotropic activity when it is present. It is probable that better regulation would be accomplished if real postovulatory-like menstruation could be produced, but to do this is still impractical owing to the cost of progesterone and the inconvenience of more injections. Recent reports indicate that estrone sulfate (Premarin) may be a more satisfactory oral estrogen than diethylstilbestrol, 2.5 mg. of the former being equivalent to 1 mg. of the latter.

Dysmenorrhea

No clear-cut program for the management of essential, primary or functional dysmenorrhea can be outlined. There are too many variables. Each case presents a different and special problem. Too often have both good and poor results followed exactly similar treatment. If the disability is sufficiently disturbing, a properly executed presacral neurectomy is at present the only means of achieving a cure.

Dysmenorrhea cannot be *cured* by hormones. Temporary relief has been obtained with trials of all the available sex hormones given at various times in the cycle and in various amounts, but the results have been unpredictable and hence not consistently confirmable.

If in the course of managing a case according to one's preference a trial of hormones is elected, predictable although limited benefit may be obtained by the following procedures.

The first of these is to inject 2.5 mg. of estradiol dipropionate intramuscularly on the fifth, eleventh and seventeenth days after the beginning of a period, which prevents the next expected period from occurring. A painful menses usually starts forty-eight to fifty-six days from the onset of the last catamenia. By this technic, half the patient's painful periods can be eliminated.

The second procedure is to give 1.0 mg. of diethylstilbestrol orally daily for twenty doses, beginning twenty-four to seventy-two hours after the onset of menstruation. This is usually followed by a painless flow at approximately the expected interval. Occasionally the expected painless flow fails to appear and in another three or four weeks a painful menses occurs. This treatment, which was worked out by Sturgis,* can be counted on to give complete relief in two out of three cycles. Its main drawback is that not all patients can tolerate the

*Sturgis, S. H. Use of stilbestrol in relief of essential dysmenorrhea. *New Eng. J. Med.* 226:371-376, 1942.

drug, which must be taken as prescribed to produce the desired effect. Diethylstilbestrol also causes vaginal discharge through stimulating the secretion of cervical mucus. It should be employed only as a temporizing measure and not indefinitely.

The third procedure is to administer the male sex hormone, testosterone. This substance is considered by many to be also a female sex hormone. Its place in gynecologic treatment is not yet settled. Some are averse to its employment; others are convinced of its safety and value in the functional disorders of women. My experience with it has been too small to allow an expression of opinion. Relief in about 70 per cent of patients with dysmenorrhea has been reported following various methods of administering testosterone, the simplest being the ingestion of 20 mg. of methyl testosterone daily for fourteen days beginning on the twelfth day of the cycle.

It is evident that alleviation of dysmenorrhea by hormones depends on sufficiently upsetting the patient's own endocrine balance. Hormone therapy, however, does no immediate or permanent harm.

Functional Uterine Bleeding

It is in patients with this disorder in its various manifestations that thyroid is especially beneficial and sometimes apparently curative. Doses approaching tolerance may have to be given.

For those whose catamenias come at approximately twenty-eight-day intervals and are profuse or prolonged or both, 10 mg. of progesterone and 1 mg. of estradiol benzoate (or dipropionate), should be injected simultaneously intramuscularly on the twenty-first day and followed on the twenty-second to the twenty-fifth day by 10 mg. of progesterone intramuscularly. Three cycles of this therapy are usually sufficient.

For the patient whose otherwise fairly normal periods are occurring at too frequent intervals, the previous procedure should be followed, beginning the injections eight days before the anticipated onset of flow and continuing them until the cycle lengthens.

For the patient who is having continuous flowing, 10 mg. of progesterone and 1 mg. of estradiol benzoate should be injected intramuscularly at once and 10 mg. of progesterone daily for the next four days. During this time the bleeding will probably decrease or cease. Two to four days later a fairly normal period will occur. Counting the beginning of this period as the first day, these injections should be repeated beginning on the twenty-first day. Treatment in this manner should be given at least twice, and it may be required again after a lapse. If the patient is bleeding profusely, rapid control is obtained by raising the daily amount of progesterone to 50 mg., reducing the dose as soon as bleeding is less, but in any event continuing injections for five days or even longer until the bleeding stops or

becomes minimal. There will follow the usual hormone-withdrawal flow and then a remission. Cyclic therapy should be continued as described above. At that point the cost of the advocated amounts of progesterone demands consideration. The objection that such therapy is of prohibitive cost may be countered by the fact that progesterone is a true female hormone, effective if given as prescribed, and that its price is being reduced.

For the patient who has a number of days of staining before the catamenia actually begins, the first procedure should be followed if treatment seems desirable.

Marked secondary anemia does occur but is unusual in women with functional flowing. Oftener it intimates the presence of a submucous fibroid, a placental polyp or a subinvolved placental site. Submucous fibroids have occurred so frequently in patients whose anemia seemed out of all proportion to the amount of described and observed flowing as to make one suspect that they may somehow be the cause of the development and absorption of some hemolytic agent. When operation for fibroids with bleeding cannot be immediately undertaken because of undue risk, testosterone propionate in doses up to 75 mg. intramuscularly weekly may be tried, with expectation of some success if a submucous fibroid is not present and of less success if one is present. This hormone is now considered by many to be of value for patients with hypertensive and arteriosclerotic cardiovascular disease. It may come to be a part of the preoperative preparation of such patients when a submucous fibroid necessitates surgery.

The hormonal treatment described is satisfactory for women before they reach their premenopausal years. Examination under anesthesia, diagnostic curettage — followed by careful exploration with a placental forceps, which may catch the polyp missed by the curet — and cervical and endocervical biopsy must, of course, often be performed before the diagnosis of functional flowing becomes clearly acceptable. A burning desire for pregnancy and extreme fear of an induced menopause are the only conceivable reasons for temporizing with the use of hormones in cases of disturbing functional flowing after the age of forty-two. Diagnostic procedures under anesthesia are practically always mandatory, and sterilization by radium at the same time is simple and effective. In fact, the increased safety of major pelvic surgery and the present-day apprehension concerning pelvic cancer, based on the frequent finding of disturbing pathologic changes — anaplasia and areas suggestive of early neoplasia — in the endometriums and cervixes of patients in the fifth decade, and on the insidiousness of adnexal cancer, are at present inducing a preference for hysterectomy and castration to radiation in this age group, especially if there is any other indication for surgery and no forbidding contraindication.

Unfortunately, pelvic cancer has developed often enough at a later date in patients sterilized by radium or x-radiation to demonstrate that this therapy should not be considered prophylactic against cancer.

DISORDERS ASSOCIATED WITH MENSTRUATION

Premenstrual Tension

Premenstrual tension or distress of minor degree is almost universal. Most women are aware of or at least evince by their conduct some of the following troubles to a greater or less degree: premenstrual irritability, apprehension, depression, mental confusion, dizziness, emotional instability, decreased efficiency, easy fatigue, headache, sense of tightness of the head ("head all tied up with iron strings," as one patient recently described it), nasal congestion, sense of abdominal fullness, backache, pelvic discomfort, aching of upper thighs, chilly sensations, swelling and soreness of the breasts, hot flushes and even localized or diffuse edema. When these troubles are disturbing enough, they are considered a clinical entity and given the above appellation.

Since premenstrual tension is more frequent and more severe after the age of thirty-five than before it, the simplest explanation is that it results from the decreased efficiency of aging ovaries in their balanced production of estrogen and progesterone. According to this point of view, it is essentially a part of the climacteric during the premenopausal years, and when it occurs in young women it may be interpreted as a premenstrual imbalance of the ovarian hormones.

The treatment suggested for this condition is to give 0.3 mg. of diethylstilbestrol orally with breakfast daily through the cycle. If relief is adequate, a dose of 0.2 mg. daily may be tried. After three months, treatment may be interrupted temporarily or permanently. No endocrine therapy has yet been worked out for those rare cases of clinically apparent premenstrual and menstrual edema.

Headache

Headache associated with menstruation is often a complaint of patients who are sooner or later found to have endometriosis. In the absence of confirmatory symptoms, signs and findings of this disease, nonincapacitating headaches may be considered and treated as part of the premenstrual tension syndrome. When, however, headaches associated with menstruation are incapacitating, resemble migraine, and yet are not controlled by ergotamine tartrate, the best treatment at present is the intramuscular injection of 1 mg. of estradiol dipropionate seven days before the expected onset of the catamenia.

Mammary Pain and Secretion

Any hormone treatment for breast complaints is emphatically to be restricted to those whose breasts

are engorged, thickened or diffusely nodular. All thought of endocrine therapy must be dispelled when a discrete mass, cystic disease or bloody secretion is encountered. These are surgical problems, with the exception of some cases of cystic change in the breasts of young women. (I recently cared for a patient with a painful cancer of the breast and axillary metastases who had been treated for three months by hormone injections and "ovary tablets.")

The simplest remedy for premenstrual soreness and swelling of the breasts is diethylstilbestrol, 0.3 mg. daily, reduced to 0.2 mg. daily as soon as relief is experienced. Some patients have chronic intermittent bilateral breast pain with premenstrual exacerbation. They are likely to be disturbed mentally, with a "breast fixation." These cases are rare. Testosterone propionate is reported to be effective, and 30 to 50 mg. is given intramuscularly weekly, beginning twelve to fourteen days before the expected period, or even through the month except during flow, for two or three cycles. Re-treatment is usually necessary after one or more months' rest from injections. Delayed periods may occur when male hormones are given during the first sixteen days of the cycle.

The management of patients with nonbloody mammary secretion is still unsettled. Secretion indicates cystic change. When to operate and how much tissue to remove are the problem. In older women simple mastectomy is the easiest solution. Unless all breast tissue is removed, periodic examination for an indefinite length of time is mandatory. In young women the secretion may be temporary, as may the cyst if it is palpable. Mammary secretion, with or without pain, in those for whom surgery does not seem necessary is said to be controlled by testosterone propionate, given as for those with painful breasts.

Midmonth Pain or Bleeding

Functional midmonth pain or bleeding is not a frequent or persistent disturbance. Thyroid is the simplest medication. Methyl testosterone, 5 to 10 mg. being given orally daily, except during menstruation, for three to five months, is said to hasten the disappearance of this ovulation syndrome.

THE MENOPAUSE

Diagnostic pelvic investigation under anesthesia for postmenopausal uterine bleeding has been more frequently required since diethylstilbestrol became the generally preferred estrogen for the treatment of the climacteric. In addition to the trouble and expense entailed by this development, these patients must be followed with special care to be sure that the flowing did indeed result from the medication, for even after careful examination under anesthesia and findings consistent with hormonal bleeding, one cannot avoid a feeling of uncertainty regarding the possibility of adnexal or intramural

neoplasm. Keeping the daily amount of diethylstilbestrol below 0.5 mg. avoids induced endometrial bleeding and practically always suffices for the control of menopausal symptoms. It is worth while remembering that painful joints are frequently a menopausal symptom that responds rapidly to small amounts of estrogenic substance.

FUNCTIONAL STERILITY

Once the husband has been shown to produce a healthy semen and the wife to have a healthy vagina and cervix, palpably normal internal genitalia, patent tubes, regular menstruation from a secretory endometrium and endocervical mucus containing a fair number of active spermatozoa three to six hours after intercourse, failure to conceive may be considered functional. In these situations, general health measures, as outlined earlier, small doses of thyroid and mild intrauterine trauma or tubal insufflation within a few hours after intercourse at about midcycle every two to three months are likely to be effective without the use of sex hormones. During the last year 3 women with functional sterility became pregnant one to six months after I had temporarily given up hope of success, having for the previous twenty-four to thirty months followed the above recommendations and in addition having employed various hormones in carefully planned trials. This sort of experience makes me diffident about offering advice, and philosophic in my attitude toward the treatment of functional sterility. At the Free Hospital for Women it has been believed for some years that the daily ingestion of moderate doses of an estrogen enhances the wife's chances of pregnancy, and 0.1 to 0.2 mg. of diethylstilbestrol is now commonly prescribed. A study of the literature indicates that there is as yet no specific hormonal means of increasing fertility in the husband. For him the best treatment appears to be an active out-of-door vacation, in addition to general health measures and the giving of thyroid.

Functional sterility sometimes exists because the wife is having anovulatory cycles, as indicated by failure to find secretory endometrium on biopsy at the beginning of flow, in which case injections as described above in the first procedure under "Functional Uterine Bleeding," should be given until a secretory endometrium is found.

MISCELLANEOUS CONDITIONS

Frigidity

Methyl testosterone, 10 to 20 mg. orally daily, has been reported as effective in those women whose

desire for and satisfaction from intercourse have waned. This medication is also stated to render them more stable emotionally and to make them feel more energetic.

Vaginitis and Pruritus, Kraurosis and Leukoplakia of Vulva

It is customary in reviews like this to describe the use of hormones in these conditions, but there appears to be no routine need for them. Vaginitis usually responds to mechanical cleansing and simple antibacterial and antiprotozoal remedies. Rarely it is necessary to resort to the daily vaginal insertion of 0.5 mg. of diethylstilbestrol for a persistent senile vaginitis.

Pruritus responds to dermatologic treatment if it is due to bacterial and fungus involvement and if the process is superficial. If the process involves the deeper layers of the vulva, and especially if it is localized in the vulval tissues, complete superficial vulvectomy is usually sooner or later necessary. Kraurosis and leukoplakia are likely to require surgery. The histologic changes of lichen planus of the vulva are similar to those of kraurosis and leukoplakia. If lichen planus is sufficiently localized and the irritation from it is not relieved by conservative means, surgery is justifiable.

* * *

For years, of course, the treatment of functional gynecologic disorders has consisted of general health measures, the giving of thyroid and of ovarian extracts and the care of associated conditions, such as anemia and infectious foci. Progress has come from the development of effective preparations of the steroid hormones and diethylstilbestrol, and from the working out of the details of their application.

8 Cumberland Avenue

DISCUSSION

DR. MARION W. WESTERMAYER, Fairlee, Vermont: Is 1 international unit of progestin equivalent in effectiveness to 1 mg. of progesterone?

A MEMBER: Would you give thyroid routinely in all cases of functional disorders, and how much do you use?

DR. W. J. P. DYE, Wolfeboro: A great many women whom I have seen are unable to take stilbestrol by mouth because of gastrointestinal symptoms and even nausea and vomiting. What do you do in this type of case, and do you have the same difficulty?

DR. SMITH (closing): One international unit of progestin is equivalent to 1 mg. of progesterone. Progestin is effective, but the synthetic hormone is cheaper and more easily available.

In regard to thyroid extract, I give it almost routinely to patients with functional disorders, usually in doses of 1 gr. or less daily.

For those patients who suffer gastrointestinal disturbance from stilbestrol, I am now changing to estrone sulfate. It costs a good deal more, but so far I have found it worth while.

METHODS OF DIAGNOSIS OF JAUNDICE*

FRANKLIN W. WHITE, M.D.†

BOSTON

A STUDY of the errors in diagnosis has already been reported¹ in 500 cases of jaundice that came under our observation on the Second and Fourth Medical Services at the Boston City Hospital during the last six years. In the present paper the clinical and laboratory methods that proved most useful in the diagnosis of these cases are reviewed. This series included most types of jaundice, such as complete and partial biliary obstruction, acute and subacute infectious and toxic hepatitis, the cirrhososes, — portal, biliary, pigmentary, toxic and cardiac, — fatty liver, tumors and syphilis of the liver, and hemolytic anemia.

On account of variation of symptoms, latent or exceptional cases, multiple diseases in a single patient and the large number of factors that go to make up the clinical picture, the number of possible combinations of symptoms and signs in any given disease causing jaundice is large, and 100 per cent accuracy of diagnosis can never be attained. The diagnosis may be laboriously built up from a collection of clues or may be obvious at once, as in arsphenamine hepatitis, prolonged painless complete obstruction and chronic low-grade familial hemolytic anemia.

HISTORY

The age incidence in four important groups is given in Table 1. In patients under thirty the cases of infectious hepatitis comprised 40 per cent, those of cholecystitis 15 per cent, and those of cirrhosis 9 per cent; there were no tumors. Infectious hepatitis may, however, occur at any age; 12 per cent of the cases occurred in patients over sixty, and the oldest of these, on whom an autopsy was performed, was eighty-seven. The large majority of cases of

TABLE 1. Age Incidence.

DIAGNOSIS	NO. OF CASES	PERCENTAGES		
		UNDER 30	30-50	OVER 50
Acute infectious hepatitis	101	40	32	27
Cholecystitis	71	15	31	53
Cirrhososes	161	9	40	51
Tumors of liver and bile passages ..	83	0	19	81

cirrrosis and cholecystitis occurred in middle life, and 80 per cent of the tumors were in patients over fifty. Painless jaundice in youth first suggests infectious hepatitis, and in patients over fifty cholecystitis, cirrhosis or tumor.

The family history sometimes strongly suggested hemolytic anemia, and sometimes gall-bladder disease or cancer.

*From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Consulting physician, Boston City Hospital.

The jaundice in the familial hemolytic cases was often slight and chronic — having been present for years. With incomplete obstruction by gallstones it was variable in duration and in degree, owing in part to the ball-valve action of stones in the common duct. In complete obstruction, which was due almost entirely to tumors, it was continuous and progressive over weeks or months until relieved by operation. In acute and chronic hepatitis the jaundice lasted for days, weeks or even months, depending on the degree of liver damage. Rarely a patient with hepatic cirrhosis remained continuously jaundiced for many months. Many patients were poor observers of the onset and variation of jaundice. (See also the paragraph on the depth of jaundice under "Laboratory Tests," below.)

Pain was important in its position, radiation, recurrence, character and relation to the onset of the jaundice. Acute and chronic hepatitis, stricture, hemolytic anemias and tumors are often described as causing so-called "painless jaundice." This is not strictly true. Pain occasionally occurred in acute and chronic hepatitis, and in rare cases was intense, with an extremely tender liver. Tumors often caused some pain, which was especially severe in the pancreas, but brief, sharp attacks of colic requiring morphine and recurring at intervals over weeks or months were much more frequent in cholecystitis and gallstones.

A history of exposure to liver poisons, such as arsenic, cinchophen, chloroform, carbon tetrachloride, gold thiosulfate and so forth, or to an infection at the onset of jaundice, was important.

Fever occurred in infection of the gall bladder, bile passages, liver or portal vein and in late cancer, and also in severe, acute hepatitis. If high and continued it was an extremely serious sign.

The distinction between acute liver disease and acute necrosis in chronic liver disease was sometimes difficult. A chronic portal or toxic cirrhosis may remain latent for so many months or years that the absence of previous symptoms cannot be relied on. Chronic disease was suggested if at the onset gross changes were found in the size, surface or density of the liver, all of which were out of proportion to the mild or moderate acute attack, or if such changes persisted long after the simple attack was over.

The course often aided diagnosis. A short course of moderate to severe jaundice (icteric index, 50 to 200) with marked loss of liver function was more frequently due to hepatocellular damage than to obstruction. The course may also be helpful in differentiating cancer from cirrhosis. If the disease is terminal, death naturally results in either disease;

if it is not terminal, cirrhosis may improve and as a result cancer can be ruled out. Complete obstruction due to cancer almost never improves, but in one exceptional case with an enlarged, hard, irregular-shaped liver the jaundice improved greatly and the gray stools became brown; a cancer of the gall bladder had ulcerated into the colon and had thus relieved the obstruction of the common duct.

Gall-bladder disease proved to be probable in patients in middle life in whom an earlier diagnosis of acute hepatitis or incipient cirrhosis had been made. The Graham test was highly useful after the jaundice had disappeared and the liver function was normal or much improved.

PHYSICAL EXAMINATION

An enlarged liver was a valuable sign of hepatic disease but gave little help in deciding on its type. The liver was usually enlarged in hemolytic anemia, passive congestion, infectious or toxic hepatitis, cirrhosis, tumor, biliary obstruction, abscess, cholangitis, fatty liver and general infections. A distinctly small liver was found in only a few cases of acute necrosis — acute yellow atrophy — or atrophic portal cirrhosis. The density and irregularity of surface was of greater diagnostic value, but opinions were sometimes conflicting owing to the difficulty of feeling the liver through an abdominal wall that was thick, rigid or distended or contained irregularly formed deposits of fat. A granular, dense liver may be described as nodular, but in this series the term was reserved for livers with nodules or irregular-shaped deposits over 1 to 2 cm. in diameter, which were found only in tumors, the nodular hyperplasia of toxic cirrhosis and hepar lobatum. There was no case of tuberculosis of the liver.

Most of the firm livers resulted in a diagnosis of cirrhosis and all the stony-hard ones in a diagnosis of cancer. In passive congestion or fatty liver, a large, smooth organ of normal consistence presented no difficulties in diagnosis.

The smooth outline of an enlarged gall bladder was occasionally lost as a result of adhesions to the bowel, omentum, enlarged lymph nodes and so forth, and the organ resembled an enlarged liver. Tumors of the right upper quadrant of the kidney, adrenal glands, colon and so forth are rarely associated with jaundice.

A dilated gall bladder is said to be found in about half the cases of tumor involving the common duct (Courvoisier's law). In 33 cases of complete obstruction, after ruling out 1 case of cholecystitis, 2 with previous cholecystectomies and 1 in which the obstruction was above the cystic duct, there remained 29 cases of malignant obstruction of the common duct. The gall bladder was palpable on repeated examinations before operation in only 9 of these. A dilated gall bladder is important in diagnosis only if it is felt, and palpation may be difficult on account of ascites or distention. Complete ab-

sence of bile from the bowel, shown by urobilinogen tests or biliary drainage, was important evidence of tumor. If there were both a large, smooth, palpable, nontender gall bladder and signs of complete obstruction, the diagnosis of tumor was practically certain.

An enlarged spleen, ascites, abdominal varices and spider angiomas all pointed toward the medical types of jaundice — acute hepatitis, cirrhosis and so forth — rather than the surgical.

A palpable spleen had definite value in suggesting hepatitis rather than tumor. In the 27 proved cases of tumor of the liver the spleen was not felt in any, whereas it was felt in 10 (27 per cent) of the 38 proved cases of cirrhosis and in many cases of severe acute hepatitis. The roentgen ray sometimes showed an enlarged spleen that was not palpable, and it was sometimes found enlarged at autopsy although not palpable during life. In the 4 cases of cancer that were diagnosed as cirrhosis, the spleen was not palpable. It was enlarged in 7 of the 15 cases of hemolytic anemia of various types.

Ascites was found in both acute and chronic hepatitis and in cancer. In the latter, the specific gravity of the fluid was usually above 1.014 if the peritoneum was involved. It was absent in obstruction due to gallstones.

Spider angiomas of the skin (Eppinger,² Williams and Snell³ and Patck et al.⁴) were found only in well-developed cirrhosis. They were the size of a nickel or dime and consisted of a group of fine arteries radiating from a common center. Pulsation was easily seen on pressure with a glass slide. The angiomas appeared only in the part of the body drained by the superior vena cava — that is, the face, neck, shoulders, chest and arms.

Biopsy of available lymph nodes was at times extremely useful.

Peritoneoscopy^{5, 18} is a valuable method of diagnosis that had only a limited use in this series. Its chief value in jaundice is the discovery of cancer or cirrhosis by vision or biopsy. The risk of biopsy is small when it is done with the electrocautery after using vitamin K. In a small number of cases the method fails because of adhesions.

The so-called "liver odor" (fœtor hepaticus²), which is marked only in acute necrosis, had a vaguely suggestive value in diagnosis.

LABORATORY TESTS

Most liver-function tests were at their best in judging the degree of damage and surgical risk and in following progress rather than in aiding differential diagnosis, but with serial tests the course of changes of the liver function had some value in diagnosis; for example, in cancer it did not clear up, in complete obstruction it became worse, and in acute, toxic and infectious hepatitis and in cirrhosis — except in very severe cases or in the late stages — it improved.

The depth of jaundice judged by the icteric index gave little or no help in single cases in deciding between obstructive and acute hepatocellular jaundice. There was a wide range, and the averages were close. In 100 cases, the icteric index was as shown in Table 2. The jaundice was often slight and

TABLE 2. *Maximum Range and Averages of Icteric Index.*

DIAGNOSIS	NO. OF CASES	RANGE OF MAXIMUM	AVERAGE MAXIMUM
Acute hepatitis:			
Infectious	17	22-250	102
Toxic	17	50-200	118
Complete obstruction	31	65-200	116
Cirrhosis and partial obstruction	35	10-225	59
Total	100		

chronic in cases of familial hemolytic anemia. The qualitative van den Bergh test, by indirect and direct reaction, also helped to distinguish hemolytic jaundice from other types. This had only limited clinical value, as already explained. The tint of the jaundice — orange, greenish, bronze and so forth — had little value in distinguishing the obstructive from the hepatocellular type.

The test for urobilinogen in the urine had more diagnostic value than did other tests because it depends on the metabolism of the liver and also on the presence of bile in the bowel. Continued complete absence for two weeks or more strongly suggested complete obstruction of the bile ducts. The urobilinogen in the urine was almost always decidedly increased at some period in the course of acute hepatocellular disease. This test was unsatisfactory in the differentiation of partial obstruction — stone, stricture and cholangitis — and chronic cellular damage.

Bilirubin in the urine usually accompanied an increased icteric index in the blood in all types of jaundice except that due to hemolytic (acholuric) anemia. This absence of biliuria in well-marked icterus was suggestive, but was a minor factor in the diagnosis of hemolytic anemia compared with the blood examination and other clinical data. The history, anemia, icterus, splenomegaly, small spherocytes, increased fragility of the red cells, reticulocytes, lack of bilirubin in the urine (usually), excess of bile pigment in the feces, and an indirect van den Bergh reaction in the blood were distinctive. The presence of bile in the urine did not rule out hemolytic anemia, since in some cases there was combined liver damage. Abundant bilirubin in the urine was found in 5 of 14 cases in which hemolytic anemia was combined with cirrhosis, gallstones or passive congestion of the liver.

Many attempts to diagnose obstructive from hepatocellular jaundice have been made by the use of various determinations, such as the total blood cholesterol and cholesterol ester, the blood prothrombin levels and their response to vitamin K,

galactose and glucose tolerance tests, hippuric acid excretion, serum phosphatase levels and cephalin flocculation tests.* There is a fundamental difficulty in this differential diagnosis; in hepatocellular damage — acute and chronic hepatitis — both metabolic and excretion tests are below normal, usually far below, whereas in pure external obstruction in the *early stages* the tests are normal or close to it, but in later stages of obstruction the lobular cells also become damaged and the tests closely resemble those of the hepatocellular group.

The total blood cholesterol was usually increased in obstructive jaundice. The prothrombin test proved an important measure of the bleeding tendency, and a low test that did not respond to vitamin K gave a bad prognosis, but the cholesterol ester levels and prothrombin tests† had only limited value in differential diagnosis. The sole diagnostic point noted in the prothrombin test was that the percentage was much more likely to rise rapidly to normal after treatment with vitamin K in obstructive jaundice and healing acute hepatitis than in chronic hepatitis (cirrheses).

Other tests that are extremely sensitive, such as the bromsulfalein and hippuric acid excretion tests, were positive in all types of liver damage and had no differential value. The bromsulfalein test was used only when jaundice was slight or absent. Occasional high retention with a low icteric index was an important sign of liver damage without indicating the kind.

The presence of bile pigment in the stools is important in estimating biliary obstruction. No test was better than a rough estimate of color with the eye except the elaborate Watson test for urobilinogen; a simplified Sparkman⁸ test also gave a rough estimate. The disappearance of urobilinogen from the urine was a useful guide to lack of bile pigment in the feces. A series of tests, done daily if desired, is far simpler than medical biliary drainage. A period with acholic stools often occurred in acute liver necrosis, but this rarely lasted more than a week — in exceptional cases two or three weeks.

Early tests for urinary diastase had great value in the diagnosis of acute pancreatitis as a cause of jaundice.

A change in the serum proteins, reduction of the serum albumin (normal about 4.5 gm. per 100 cc.) and lowering or reversal of the albumin-globulin ratio (normal about 2.0) were found in nearly all cases of well-marked disease of the liver and seemed to run parallel to the extent of liver damage. This change may be looked on as an index of liver failure and is highly valuable in the prognosis of chronic liver disease, as well shown by Post and Patek,⁹ but has little or no value in single cases in diagnosing the type of disease — whether acute or

*The cephalin flocculation test⁶ was used in only a small number of recent cases.
†Quick's⁷ one-stage method for prothrombin was used.

chronic hepatitis, cancer of the liver or external obstruction. This is clearly shown in Table 3.

The range of the serum albumin and globulin levels and of the albumin-globulin ratio was similar in the four groups of cases, and the values in single cases apparently depended on the severity of the

TABLE 3 Serum Protein Values in 50 Consecutive Cases

DIAGNOSIS	NO OF CASES	SERUM ALBUMIN gm 100 cc	SERUM GLOBULIN gm 100 cc	ALBUMIN GLOBULIN RATIO	AVERAGE ALBUMIN GLOBULIN RATIO
External obstruction (gallstone or cancer)	11	15-5.2	19.27	0.313	1.0
Acute hepatitis	11	17-4.7	18-4.4	0.622	1.4
Cirrhosis	22	15-4.5	21-6.4	0.3-1.6	0.8
Carcinoma of liver	6	14-3.2	24-4.8	0.4-1.2	0.6
Total	50				

illness rather than on the type of disease. All the cancers of the liver were fatal, as were 20 of the 22 cirrhotics, 6 of the 11 external obstructions and 5 of the 11 cases of acute hepatitis.

A positive blood serologic reaction in jaundiced patients does not usually indicate syphilis of the liver. Hepatic cirrhosis and syphilis of the liver are often associated in the literature. In the present series, of 38 cases of cirrhosis with jaundice that came to autopsy there were 7 cases (18 per cent) with a positive Kahn or Hinton reaction but no evidence of syphilis of the liver. In 13,219 general autopsies at the Boston City Hospital between 1928 and 1937 there were 487 cases of cirrhosis of the liver and only 18 cases of acquired syphilis of the liver,* making the percentage of syphilis of the liver 3.7 per cent among the cirrhotics and only 0.14 per cent in the total group. McCrae's¹⁰ statement that syphilis of the liver should be considered in every case of hepatic disease in which the diagnosis is obscure probably applies to the pre-Wassermann days, chiefly covered by his figures, when only 1 case in 7 was recognized clinically. This is at present evidently a rare disease.

Since the only known case of syphilis of the liver in this series showed a negative Hinton reaction and all the other cases with positive Hinton reactions that came to autopsy or operation showed no syphilis of the liver, it cannot be said that the blood serologic test was of much help in this diagnosis. In the last ten to twenty years, most jaundice in syphilitic patients has been due to toxic hepatitis following the use of arsenic in treatment.

The roentgen-ray examination often detected disease of the gall bladder or the primary source of a cancer of the liver, and the discovery of early esophageal varices occasionally aided the diagnosis of cirrhosis before other signs were clear. The Graham test cannot be relied on during an attack of jaundice, when the liver function is usually low and the dye is poorly excreted; the test should if possible be made between attacks of jaundice. Biliary

drainage was not extensively used on account of the time required, but it has special value when there is too much jaundice — and too poor liver function — for a Graham test.

No laboratory test was diagnostic without the clinical background. Improved diagnosis with the addition of laboratory tests was sometimes due not wholly to the tests but partly to more intense study of cases and added clinical experience. At the present time especially, tests with a simple technique easily available to the practitioner or small hospital have the preference. For a fuller discussion of liver-function tests and laboratory data, the reader should consult recent papers on this subject.¹²⁻¹⁷

The discovery of primary cancer of the liver, which develops chiefly in cirrhosis, is difficult by any method. The clinical pictures of late hepatic cirrhosis and primary cancer (hepatoma) are closely similar — namely, gastrointestinal symptoms, discomfort or pain in the right upper quadrant, weakness, loss of weight, hematemesis, fever, jaundice, ascites, anemia, enlarged liver, positive roentgen-ray examination and low liver function. There seems little or no possibility of succeeding in this differential diagnosis unless there is an external nodule or nodules in the liver that can be palpated or discovered on its surface by the roentgen ray or peritoneoscope, or unless there are metastases.

During the last six years we have seen 2 proved cases of primary cancer of the liver in patients with cirrhosis. In one, that of a man of sixty-four with jaundice, the evidence pointed equally to cirrhosis and to massive cancer of the liver from an unknown source, and both diagnoses were given equal value. In the other, that of a Chinese of sixty-six, a diagnosis of hepatic cirrhosis and cancer of the esophagus, with metastases to the lung, pleura, lymph nodes and bones, was made. At autopsy, cirrhosis, primary cancer of the liver, epidermoid cancer of the esophagus and a teratoma of the lung with adenocarcinoma were found.

SUMMARY AND CONCLUSIONS

The course of the jaundice often aids diagnosis, and since cases of jaundice are rarely emergencies, a short study period is useful. Tests of liver function should be repeated in series.

A short course of moderate to severe jaundice with marked loss of liver function was due oftener to hepatocellular damage than to obstruction. Acute deep jaundice with brown stools was almost always of the hepatocellular type.

The value of the depth of the jaundice, the size of the liver and a palpable gall bladder were often overestimated in differential diagnosis. The icteric index in acute hepatitis and complete external biliary obstruction were much alike. An enlarged liver was a valuable sign of hepatic disease, but was of such common occurrence that it gave little help in deciding the kind. The gall bladder could be

*All these syphilitic livers in adults showed more or less fibrosis and were classified as syphilitic cirrhosis.

palpated in only one third of the cases of malignant obstruction of the common duct; complete absence of bile from the stools was far more frequent and constituted important evidence of obstructive tumor. Complete obstruction due to cancer almost never improved.

The spleen was not palpable in any case with tumor of the liver, but was felt in 27 per cent of the cirrhotic cases. Spider angiomas were found only in portal cirrhosis. Fever and leukocytosis in late cancer sometimes simulated cholangitis and liver abscess. In deep jaundice an absence of bilirubin in the urine suggested hemolytic anemia, a diagnosis that was readily confirmed by other tests.

The test for urobilinogen in the urine often gave direct help in diagnosis of complete obstruction from hepatocellular damage and from partial obstruction. Other tests, such as hippuric acid and bromsulphalein excretion, were positive in all types of liver disease and had no differential value. Some tests that are useful in prognosis and for which differential value has also been claimed, such as the amount of cholesterol ester in the blood, the prothrombin level and its response to vitamin K and changes in the levels of serum proteins and in the albumin-globulin ratio, had little or no differential value.

In the diagnosis of acute pancreatitis with jaundice, early tests for diastase in the urine proved simple and highly valuable.

Positive Hinton, Kahn or Wassermann reactions in jaundiced patients usually did not indicate syphilis of the liver.

The roentgen ray often detected gall-bladder disease, the primary source of a cancer of the liver and esophageal varices. During deep jaundice the

Graham test had little value on account of poor excretion of the dye by the liver.

I am indebted to Dr. Emmanuel Deutsch for many liver function tests done in the Surgical Research Laboratory Boston City Hospital.

THE THERAPEUTIC VALUE OF TWO NEW SULFONAMIDE COMPOUNDS, SUCCINYL-SULFATHIAZOLE AND PHTHALYLSULFATHIAZOLE, IN EXPERIMENTAL TRICHINOSIS*

DONALD L. AUGUSTINE, ScD†

BOSTON

DESPITE the wide and successful use of sulfonamide compounds in the treatment of bacterial infections, they have not been found to be particularly promising as therapeutic agents in diseases caused by animal parasites. It must be admitted, however, that present knowledge of the value of these drugs in the treatment of parasitic diseases has scarcely advanced beyond the experimental stage. It has been shown that sulfanilamide is a complete sterilizing agent against the malarial parasite *Plasmodium knowlesi* in rhesus monkeys, but it is not usually effective in human malaria due to *P. falciparum*,¹ whereas both promin and sulfadiazine are definitely active against the three common species of human malaria.² Encouraging results have been obtained with sulfaguanidine used to combat coccidiosis in chicks,³ lambs⁴ and calves.⁵ Critical tests with sulfanilamide derivatives against amebic infections have not been performed. Fairley,⁶ however, noted that amebic ulcers heal during sulfaguanidine therapy, but that they relapse after cessation of treatment. Keil⁷ observed no effect on the numbers of bancroftian microfilariae in the blood of 9 lepers treated with Prontosil. McCoy⁸ found sulfanilamide to be entirely ineffective in the treatment of trichinosis in rats.

At the present time there is no specific treatment for trichinosis. Constant world-wide search has utterly failed to find an anthelmintic that will remove the adult worms from the intestinal tract or destroy the larvae in the blood stream and muscles.

The physical properties of two new sulfonamide compounds, succinylsulfathiazole (sulfasuxidine) and phthalylsulfathiazole (sulfathalidine), are such that they suggest possible anthelmintic activity. Both are sparingly absorbed from the gastrointestinal tract, and a high concentration can be maintained in the diseased intestine without causing untoward toxic manifestations.^{9, 10} They have extremely high bacteriostatic properties, their action being essentially limited to the local effect on the contents of the gastrointestinal canal.¹¹ It therefore seemed important to determine whether these drugs also had anthelmintic properties in trichinosis, especially against the intestinal stages of the parasite.

The tests with both drugs were similar. A single experiment was made for each drug in the following manner:

Five guinea pigs each weighing approximately 260 gm., were forcibly fed approximately 3000 infective *Trichinella*

larvae. Two days later at which time the worms had approached sexual activity in the small intestine,¹² treatment of 3 of the animals was started. Food was withheld for fifteen hours prior to treatment but was replaced again after the first administration of the drugs. Each of the 3 treated guinea pigs received by a stomach tube at 9 a.m., noon, 3 p.m. and 6 p.m., on two consecutive days, 0.5 gm. of one or the other of the drugs† suspended in 1 cc. of water. Three days after treatment was begun, or five days after the infective feeding, 1 of the untreated and 2 of the treated animals were sacrificed and their intestines examined for adult parasites. The remaining animals, 1 untreated and 1 treated, were sacrificed thirty days after receiving the infective larvae. Direct microscopic examinations for encapsulated trichinae were made on bits of masseter and diaphragm muscles pressed between two glass slides.

The dosage used was arbitrarily determined. Poth and Knotts⁹ fed dogs 1 gm. of succinylsulfathiazole per kilogram of body weight daily in six divided doses for ninety-five days without the development of toxic manifestations. A marked lowering of the number of coliform bacteria occurred after twenty-four hours and persisted throughout the experiment. According to Poth and Ross¹⁰ phthalylsulfathiazole has two to four times the bacteriostatic activity of succinylsulfathiazole. It is believed, therefore, that our dosage, approximately 8 gm. per kilogram a day for two consecutive days, was adequate to demonstrate any trichinocidal effect of these drugs.

The results obtained from both drugs were essentially the same. No deaths occurred among the untreated and treated animals. The untreated animals showed no signs of trichinosis. Loss of appetite, loss of weight and transient soft stools were characteristic developments among all the treated animals. These were believed to be toxic manifestations of the drugs.

Adult worms were equally numerous in the intestines of both untreated and treated animals. The worms were alive and normally active, and the females were gravid with living embryos. Both animals sacrificed thirty days after infection appeared equally parasitized with encapsulated trichinae. Thus, no evidence was obtained that either succinylsulfathiazole or phthalylsulfathiazole has any value in the treatment of trichinosis.

SUMMARY

The effect of two new sulfonamide compounds, succinylsulfathiazole and phthalylsulfathiazole, in the treatment of experimental trichinosis is described.

The experiment showed that neither succinylsulfathiazole nor phthalylsulfathiazole is of any value in the treatment of trichinosis.

*The compounds for this test were supplied by Sharp and Dohme Incorporated Philadelphia.

†From the Department of Comparative Pathology, and Tropical Medical Service, Harvard Medical School and Harvard School of Public Health.

†Associate professor of comparative pathology and tropical medicine, Harvard Medical School and Harvard School of Public Health.

MEDICAL PROGRESS

MALARIA IN MASSACHUSETTS

VLADO A. GETTING, M.D., DR.P.H.*

BOSTON

MALARIA has been known to exist in Massachusetts from the earliest colonial times. Unfortunately, the malarial parasite and the transmission of malaria by mosquitoes were not discovered until the latter part of the nineteenth century. Consequently, it is difficult to determine the magnitude of the malaria problem in Massachusetts previous to that time, since many clinical entities were confused because of the lack of diagnostic refinements. There is, however, a certain amount of information concerning the prevalence of intermittent fever, ague, bilious fever, malignant fever, pond fever or mortal fever, as malaria was variously called in earlier times. Perhaps the completest early account of malaria in Massachusetts is to be found in the Boylston Prize Dissertations of 1836, in which Oliver Wendell Holmes¹ presented a paper entitled "Indigenous Intermittent Fever in New England." This paper was based on a review of the previous writings on the subject and personal communications from physicians.

From his search among the early writings on medical history in New England, Holmes concluded that intermittent fever existed in at least several places in New England but that the records of its existence in the literature were scanty and inaccurate. The second portion of his paper consists of replies to inquiries that he had sent to physicians throughout New England. This method of surveying the malaria situation was more fruitful, and Holmes gathered a large amount of disconnected information on the prevalence of intermittent fever in this region. In many cases, there can be no doubt that the disease concerned was malaria. In some accounts it is apparent that it was tertian malaria. Many of these outbreaks of intermittent fever were due to movements of population, concerned mainly with new construction, in particular dams, and the drainage of marshes.

The first epidemic of malaria in Massachusetts took place at the close of the eighteenth century and existed in the western portions of both Massachusetts and Connecticut along the Housatonic River basin. The second epidemic appeared from 1828 to 1832 in Connecticut along the shore of Long Island Sound, and slowly moved in a northeasterly direction, eventually reaching western Massachusetts. No appreciable number of cases were reported in Massachusetts after 1836. The third epidemic began in New Haven about 1850 and remained within the vicinity of Long Island Sound for the ensuing fourteen years. In 1865, the disease began to spread northward, and it first appeared in Massachusetts in Springfield in 1870. During the ensuing nine years malaria spread in a northerly direction up the Housatonic and Connecticut rivers.

In 1880, Adams² made a survey of the malaria situation since 1836, by means of correspondence, personal observation and inquiry. By this means, the existence of malaria was ascertained in forty-eight cities and towns, and its absence in one hundred and sixty-three. There were no replies from one hundred and twenty-eight towns, but the author states that replies were received from almost every place of any size or importance.

In 1884, Chapin³ wrote a paper entitled "The Origin and Progress of the Malarial Fever Now Prevalent in New England." He gave data on the occurrence of malaria in Massachusetts in 1881, 1882 and 1883. In 1881, malaria reappeared in the towns where it had appeared the previous year, with an increase in the number of cases and in mortality. Chapin remarks that the term "malaria" was beginning to replace the term "intermittent fever" in Massachusetts. In 1882, malarial diseases continued in the same towns, with an increase in deaths. In 1883, there was a general decrease in the number of cases, although nothing had been done in the way of sanitation to secure the result. Chapin judged

*Commissioner, Massachusetts Department of Public Health; lecturer in public health practice, Harvard School of Public Health.

that the decrease in malaria was entirely dependent on natural causes.

In 1889, Cook⁴ made a study of malaria in eastern Massachusetts. He concluded that prior to the previous four years malaria as an epidemic disease was unknown in eastern Massachusetts. The then prevailing epidemic was in reality a continuation of the epidemic of the seventies that had occurred in the western part of Massachusetts. Since the summer of 1885 at least twenty-two cities and towns in the counties of Middlesex, Norfolk and Worcester, not counting those where there had been sporadic cases,

concluded that whereas typhoid fever and other diseases had possibly complicated the picture, malaria did exist in the various epidemics that had been described by the several writers. He decided that the origins of the various epidemics could be discovered only by a careful study of contemporary local history, with special reference to movements of population and modes of living. He contended that even without any appreciable influx of immigrants from countries in which malaria was prevalent, the southern states could at any time have furnished a sufficient quota of malaria carriers to start an

FIGURE 1. Malarial Death Rate in Massachusetts.

reported the prevalence of malaria. These towns were distributed along the Charles, Sudbury and Blackstone rivers.

In 1903, Smith⁵ published in the *Boston Medical and Surgical Journal* a series of articles entitled "The Sources, Favoring Conditions and Prophylaxis of Malaria in Temperate Climates, with Special Reference to Massachusetts." Since the relation of mosquitoes to malaria as carriers was established by that time, and since the malarial parasite had been discovered, the diagnosis of malaria and the study of its spread are more reliable in the work of Smith than in that of the earlier writers mentioned. Smith made a survey of mosquitoes in Massachusetts and found *Anopheles maculipennis*—which was apparently confused with *Anoph. quadrimaculatus*—to be the commonest mosquito of any of the anophelines. He discussed the life, habits and breeding places of this mosquito, together with those conditions that favor mosquito breeding. Finally, he reviewed the history of malaria in Massachusetts and its status at the time in the light of the biological discoveries mentioned above. Smith

epidemic under favorable local conditions. According to this author, the last invasion of New England by malaria, which began, roughly, in the sixth decade of the nineteenth century and extended through the first decade of the twentieth century, was largely due "to the great material development which found expression in many new public and private enterprises, such as the construction of railroad beds and highways, the introduction of public water supplies and sewerage plants, the building of mills and the drainage, filling and grading of suburban territory and the like." In connection with these enterprises, the sources of infection during the preceding thirty years he regarded as coming from the Italian, Hungarian and other immigrants from endemic foci and the contingent of Negro laborers from the southern states.

In 1926, Quinn⁶ made a study of malaria in New England by mailing questionnaires to the health department of each of the New England states, to sixty-five representative cities and towns and to a number of hospitals. He pointed out that anophelines existed in all parts of New England below

a 2000-foot altitude, but that the mosquito is merely the connecting link between the malarial patient and the noninfected person. The plasmodium of malaria was brought in by immigrants from malarious sections of the world. Rigorous winters, cool summers and mosquito-control measures, however, together with quinine medication, prevented the completion of the necessary chain of malarial patient, mosquito and noninfected person. The author reported the existence of an epidemic focus of malaria in Manchester, New Hampshire,

malaria began to manifest itself in 1880 and continued until 1898, when the deaths again began to decrease. This second wave of deaths from malaria, as recorded in these reports, was caused by three factors. The first was the epidemic of malaria in Massachusetts that has already been discussed. The second was the effect of the Spanish-American War on this disease, which was seen in the peak of 1898; during this year many soldiers returned to Massachusetts after contracting the disease in Florida or Cuba. The third comprised better diagnostic facilities, in part due to the increased knowledge concerning malaria. The plasmodium was demonstrated during this period, and the mosquito transmission of malaria was proved, as well as the mosquito transmission of yellow fever.

With the turn of the twentieth century, deaths from malaria began to decrease rapidly, reaching a new low in the late 1920's. These deaths have averaged 1.8 per annum during the last ten years, indicating a case fatality of 8.9 per cent on a basis of the reported cases over the same period.

Morbidity statistics. It was not until 1914, however, that malaria itself was made reportable, when the Massachusetts Department of Public Health declared it to be a disease dangerous to the public health. At that time malaria was endemic in several places within Massachusetts.

In 1915, the first year for which the figures are complete, the reported incidence of malaria was the greatest. Since then the disease has a continued decreasing trend (Fig. 2) and reached an extremely low level in the five years immediately preceding the present war. Since 1941, however, there has been a continuous increase in the number of reported cases. Malaria was prevalent in Boston from 1915 to 1928. Most of these cases were in sailors who had acquired the infection in the tropics and were hospitalized in this city. Some of the cases, however, were connected with a new sewer project where Italian labor was employed. The high incidence of malaria in Chelsea from 1928 to 1935 is explained by the fact that the United States Marine Hospital was located there and received many sailors from foreign countries. The epidemic of 1918 in Ayer was due to the presence of large numbers of troops at Camp Devens some of whom were from the South.

In all there are three areas in Massachusetts where malaria has existed within the last twenty-five years. In each instance the disease ceased to be endemic in the area about twenty years ago. These areas are as follows:

The Charles River drainage area. The disease was prevalent here from 1915 to 1921. It apparently occurred first in Natick and Newton and spread to the neighboring communities of Dedham, Framingham and Wellesley. The town of Dedham has a large Italian colony. This is also true of Milford, in the upper part of the Charles River area, where malaria was prevalent from 1919 to 1924. Older residents of this part of the Charles River basin state that malaria was common in their childhood during the first

FIGURE 2. Reported Cases of Malaria in Massachusetts.

and in Connecticut, and also the incidence of malaria in several communities in Massachusetts, totaling 445 cases during the period 1917-1924.

Present Status of Malaria

Mortality statistics. Deaths from malaria were made reportable as early as 1842. At first these were reported as "intermittent fever" and "remittent fever"; from 1855 to 1900 the terminology was changed to "ague" and "remittent fever," and from 1901 to 1911 to "intermittent fever" and "malarial cachexia." Finally, since 1912 the disease has been reported as "malaria."

A study of these reported deaths (Fig. 1) reveals that there have been several peaks during the last hundred years. The first peak was reached in 1864 and was associated with an importation of the disease in Union soldiers who returned from the Civil War. A second increase in deaths due to

decade of the twentieth century. It is not unlikely that it may have been a hang-over from the epidemic wave of the last quarter of the nineteenth century. Probably there have been many more cases of malaria in this region than were reported.

The Blackstone River basin. Malaria was endemic in this region from 1915 to 1921, particularly in the towns of Uxbridge, Douglas and Northbridge.

The Taunton River basin. Here malaria persisted from 1915 to 1922. The same etiologic factors were responsible for disease in these regions as in the Charles River drainage area.

Malaria acquired in Massachusetts. The Massachusetts cases can be divided into two major groups, intrastate infections and out-of-state infections

sets. Doubtless, these infections were acquired from gametocyte carriers who infected the mosquitoes in the vicinity of the victim.

During the last fourteen years, 6 patients have acquired malaria as a result of transfusions. To prevent a repetition of this unfortunate accident and the similar transference of syphilis, under a law⁷ passed by the Massachusetts Legislature in 1938, the Department of Public Health made regulations relative to transfusions. On April 10, 1939, these regulations⁸ became effective. The regulation reads, "No person shall introduce the blood, or any

of the Commonwealth. Moreover, most of these were cases induced in the treatment of syphilis of the central nervous system. Since 1930, a total of fourteen years, there have been only 11 cases that were probably naturally acquired within the Commonwealth. These patients were presumably bitten by *Anopheles* mosquitoes that were carriers of malaria. These cases were scattered throughout the Commonwealth (Table 2), and there is no evidence that there was any connection between them. In some cases—namely, the two children who acquired the infection during 1938—there were malaria cases in the same or a neighboring household. The source of the infection in the other 9 cases, however, has not been established. Malaria is certainly not epidemic in this state, nor can it be said to be endemic. The number of naturally infected cases averages less than one a year, and the disease can therefore be called a rare phenomenon in Massachu-

setts. Of the cases of malaria reported in Massachusetts since 1930, over 75 per cent were acquired beyond the limits of the Commonwealth. During peacetime, these patients were civilians who had traveled in the southern United States or had visited tropical or subtropical countries. The largest group of out-of-state cases was reported by the United States Marine Hospital among merchant seamen who stopped at African ports. Since 1941, however, a new and important importation of cases has occurred. These are servicemen of the armed forces and prisoners of war. The vast majority of cases (95 per cent) reported in 1943 were from military organizations or among servicemen who were home on leave and developed symptoms of malaria after their arrival in the State.

Vectors of Malaria

During the summer of 1939, the Massachusetts Department of Public Health conducted, in cooperation with the Work Projects Administration, a survey of mosquitoes that were vectors of disease. This investigation was made on the recommendation of Brigadier General J. S. Simmons, then assistant surgeon of the First Service Command, United States Army, following an outbreak of equine encephalomyelitis involving about 300 horses and

34 human beings.^{9, 10} The survey determined the seasonal and geographical distribution of the fifty-six species of mosquitoes in Massachusetts, collected data on their life habits, and determined the epidemiologic importance of the various species. The conclusions reached were based on 49,084 collections comprising 278,557 specimens.¹¹ These mosquitoes and the accompanying data were gathered

house mosquito, and *Mansonia perturbans*, which is most numerous in early summer. It has been collected in all parts of the Commonwealth and represents about one fourth of all Anopheles. Three other anophelines, *Anoph. maculipennis*, *Anoph. walkeri* and *Anoph. crucians*, transmit malaria and act as important vectors in other parts of the world. In Massachusetts all three of these are rare and

by one hundred WPA collectors and numerous volunteers enrolled with the co-operation of various federal and state institutions, local boards of health and other organizations.

Only two of the nine genera of biting mosquitoes of Massachusetts are known to contain species that may act as vectors of human disease. The statistical importance of these genera varies greatly (Table 3). *Culex* mosquitoes comprise 77 per cent of all mosquitoes and do not transmit any known disease of

epidemiologically unimportant in the transmission of malaria. *Anoph. punctipennis*, although a possible vector of malaria, because of its large numbers may play a role as a vector. It is distributed throughout the Commonwealth, is about three times as numerous as *Anoph. quadrimaculatus*, and breeds almost any type of water collection, clear or for large or small.

From these observations, the possibility of an outbreak of malaria can be visualized. The vectors

*Too small or too damaged for identification

man in Massachusetts. *Aedes* represent 7 per cent of the mosquitoes, and of the twenty-one species in this genus, six have been shown to transmit the Eastern strain of equine encephalomyelitis in the laboratory.^{11, 12} All the other genera except *Anopheles* comprise less than 5 per cent of the mosquitoes, and none of them are vectors of the disease. The genus *Anopheles*, comprising 12 per cent of the mosquitoes, is responsible for the transmission of malaria. In Massachusetts this genus is represented by five species, one of which, previous to the survey, was not known to inhabit Massachusetts (Table 4).

Anoph. quadrimaculatus is the most important vector of malaria in Massachusetts. It is an ubiquitous breeder but prefers large, clear bodies of water. Most numerous in July and August, it is a vicious biter and enters buildings oftener than any other mosquitoes except *Culex pipiens*, the common

malaria are present in all parts of Massachusetts. With susceptible persons likewise present, only one additional factor is needed to complete the cycle, namely, gametocyte carriers.

Epidemiology

From the study of malaria in the past and the present status of the disease in Massachusetts, it can be concluded that malaria has existed in this state as an endemic disease for many years in both the eastern and western portions, that it has crept over portions of the Commonwealth in at least three epidemic waves, that it has been practically eradicated from Massachusetts and that, at the present time, it is not a public-health problem. If the absence of malaria from Massachusetts could be depended on, there would be no justification in raising this problem at the present time.

Fortunately, climatic and environmental conditions in Massachusetts are unfavorable for the continued endemicity of malaria. Although there have been epidemic periods in the past, the disease has almost disappeared between these times of high prevalence. Each year, Massachusetts¹³ becomes less favorable for the breeding of *Anopheles* mosquitoes. Ponds are kept clear of vegetation offering protection to the larvae; marshy areas about ponds and streams are gradually filled; and with the building of each new house more land is graded and more mosquito-breeding places are destroyed. These factors, limiting the breeding of vectors, and the excellent screening of houses and the prompt treatment of cases of malaria undoubtedly play important roles in preventing a major outbreak.

Malaria, however, increased to epidemic proportions following the Civil War and the Spanish-American War, when servicemen returned from malarious areas, bringing the infection with them. During World War I, although malaria was prevalent among the troops in southeastern Europe,¹⁴ our forces did comparatively little fighting in areas of endemic malaria. Consequently, as Simmons¹⁵ points out, there was only a slight increase of malaria in the United States Army and this was quite transient. In turn, there was practically no transmission of the disease from the military to the civilian population, and Massachusetts malaria rates were practically unaffected by the war of 1914-1918. Other parts of the world, however, were less fortunate. Malaria returned to plague areas in Europe, from which it had disappeared for years, and Russia experienced the most terrible epidemic of modern times.¹⁴

Malaria and the War

In the present war,¹⁶ the importance of malaria cannot be minimized. The surrender of Bataan can be, at least in part, ascribed to malaria and the lack of quinine. Practically all the South Pacific islands are free from malaria except those between the Equator and latitude 20°S. from New Guinea east to longitude 170°E.¹⁷ Malaya,¹⁸ Burma,¹⁹ India, Africa and the entire Mediterranean basin are rife with malaria.

The Army has taken all possible precautions to control malaria.²⁰ Under battle conditions,²¹ however, exposure to malarious mosquitoes is inevitable, and consequently many soldiers, sailors and marines have acquired the parasites. Geiman²² has reviewed the advances in research and their application to the malaria problems facing the entire world as a result of this war. On the return of these soldiers to the United States and to their homes or to hospitals, there is danger of spreading the disease to civilians. The danger of introducing malaria to Massachusetts,²³ to New York,²⁴ to other parts of the United States²⁵ and to Australia,²⁶ in fact to almost any region where anophelines are known to exist,²⁷ has been pointed out by numerous authors.

Through a program entitled "Malaria Control in War Areas," the United States Public Health Service²⁸ has been conducting a project designed to control breeding of disease-bearing *Anopheles* mosquitoes and to reduce potential malaria transmission in extracantonment zones of military establishments and in essential war industries. Up to 1943, the vast majority of this work was limited to the area south of the Mason and Dixon Line. Recently, as a result of surveys of mosquitoes made in the vicinity of certain military establishments in Massachusetts, the program has extended its activity into New England.²⁹ This organization³⁰ is giving special attention to areas adjacent to Army general hospitals where casualties from malarious areas may be quartered. Some of these hospitals are assisted by active control measures, others are undergoing entomologic surveillance, and in some, surveys have been completed. Similarly, prisoner-of-war camps are being surveyed and in some instances assisted with malaria-control programs. Thus far, only entomologic surveys have been made in and about military establishments in Massachusetts. In several instances, however, control measures have been instituted in military establishments against mosquitoes primarily as pests.

The Massachusetts Department of Public Health and the Reclamation Board³¹ have been co-operating with the armed forces and with the control program of the United States Public Health Service described above in making surveys of the extracantonment areas of military establishments in this state. Thus far, the expenditure of money for mosquito control in Massachusetts has been directed at the nuisance and pest angle and not specifically against vectors of disease. As yet, in Massachusetts, no funds have been expended specifically against the anophelines. Data, however, are being assembled to enable efficient control measures against anophelines as soon as a need for these develop. In one instance the personnel of the Massachusetts Reclamation Board have been active in instructing a large number of troops in mosquito-control measures so that they in turn may become proficient in applying these measures against *Anopheles* when they go abroad into zones where malaria is prevalent.

The reintroduction of malaria into Massachusetts may come from three sources. The first of these is the presence of carriers of the usual strains in large numbers, thereby giving rise to cases in the immediate vicinity. If patients are properly treated and are kept under screens, especially after dusk, this danger can be reduced to a minimum, especially when combined with measures designed to reduce the anophelines below the level necessary for endemicity. Any such outbreak will be temporary and limited in geographical area, since the factors that are responsible for the eradication of malaria are still in operation and will again eradicate the disease. The second source is new species of mosquitoes that are better

vectors, which may be brought by airplanes and ships and thereby enhance the spread of the disease. The classic illustration is the introduction of *Anoph. gambia* from Africa to Brazil and the subsequent epidemic of malaria.^{32, 33} More recently, *Anoph. albimanus* was discovered in an area adjacent to a Florida airport³⁸; since this species is not native to Florida, there is only one explanation for its presence near the airport. Active disinsectization of all airplanes and ships from malarious areas is the only sure safeguard against bringing new vectors into Massachusetts. The third source comprises new species or strains of malarial parasites introduced either by human carriers or by mosquito vectors. Such a plasmodium, if it finds a more efficient vector, may create a serious outbreak.

Malaria Control

Adequate control of malaria must be based on one or more of the following procedures: control of mosquito vectors; protection from the bites of infected mosquitoes; immunization of susceptible persons; removal of sources of infection of mosquito vectors by isolation of cases or treatment of carriers; and prevention of entry of mosquito vectors and possible sources of infection into areas as yet unaffected by the disease.

Mosquito control. Certain conditions are necessary before a mosquito-borne disease can become epidemic or reach a high endemic index. One of these conditions is the existence of a numerical relation between the hosts, vectors and susceptible persons. When this relation is upset by a reduction of the number of vectors, the disease ceases to be epidemic and rapidly declines, either arithmetically or geometrically, depending on the interrelation of many factors. It becomes apparent that a moderate reduction in the number of mosquitoes below the critical level will markedly reduce the prevalence of the disease in an area where there are many immune persons, but in a region with many susceptible persons the reduction below the critical level must be much greater. This concept was developed by Ross,³⁴ who applied it to malaria. Carter³⁵ and Gorgas³⁶ applied it to yellow fever.

The bionomics of mosquitoes³⁷ are such that control measures must be designed to eliminate or control the larvae or the adults. The measures that are most effective in any area depend on the local factors and on the species of mosquitoes concerned. It is impractical and uneconomical to attempt to control all mosquitoes. The control measures must be directed against the species that it is desired to reduce below the critical level. Therefore, in order to ensure effective control measures, it is important to understand the bionomics, breeding habits, seasonal and geographical distribution and identification³⁸ of the species that are concerned with the transmission of the disease. Since local circumstances vary, it is necessary that a mosquito survey³⁹

be made before control measures are introduced into a new area for the purpose of controlling mosquito-borne disease. Even in controlling mosquitoes as a nuisance, it is necessary to determine their bionomics before an economical and efficient nuisance control can be expected.

Protection from mosquitoes. Effective protection from the bites of mosquitoes can be accomplished only under extremely limited conditions, especially in combat.⁴⁰ Screening and avoidance of unnecessary exposure are the most effective methods. Spraying in houses, and out-of-doors, the application of mosquito repellents and the killing of adult mosquitoes are adjuvants. For this method to be completely effective, man would necessarily have to remain behind screens at all times. Since this is practical impossibility,⁴¹ protection against mosquito bites is only partial.

Immunization of susceptible persons. There is specific immunization against malaria. The suppressive treatment with quinine or atabrin is an attempt to destroy or suppress the multiplication of the plasmodium as soon as it is introduced into the blood stream. These drugs merely act as suppressives and not as prophylactics, and are not recommended for residents in Massachusetts. Atabrin⁴² is about as effective as quinine⁴³ in preventing clinical attacks of the disease, and both drugs⁴⁴ are being used in combat areas. Plasmoquin⁴⁵ has proved valuable as a suppressive and is not recommended for prophylactic use. The development of a good prophylactic against malaria would be one of medicine's greatest gifts to humanity.

Removal of human sources of infection. Removal of human sources of infection is effective only to a limited extent. Patients with the disease or gametocyte carriers, with the infecting agent in the circulatory blood, may act as foci of infection for vectors, and are usually the foci of outbreaks of disease in new areas. It is therefore sound preventive medicine to isolate these persons in mosquito proof quarters.

Prevention of entry into new areas. Malarial patients entering the country from abroad should be maintained under observation at least three weeks after the stopping of suppressive treatment with atabrin or quinine, since most cases develop symptoms by that time. The patients should receive adequate therapy in screened quarters,⁴² and a discharge from the hospital must be followed in order to detect recurrences adequately. In this way, most of these patients will be rendered non-infectious to mosquitoes and will not act as foci for local outbreaks.

Airplanes must be adequately treated to prevent the importation of infected mosquitoes. With the increase of speed of travel, many planes may transport patients from one continent to another within the incubation period of disease. New quarantine regulations and procedures to protect the Nation

CASE 30121

PRESENTATION OF CASE

A forty-seven-year-old housewife entered the hospital because of pain in the lower back.

The patient had been in apparent good health until one year prior to entry, when, following a cold, she developed a burning pain over the sacrum and lower back. Similar attacks recurred and apparently progressed in severity. Recently the attacks had lasted for three or four days and had forced her to remain in bed. She felt that she was never free of pain, although it rarely kept her awake. During acute attacks, hot packs and aspirin gave relief. About eight months before admission she noticed that the pain radiated to both legs. This was brought on chiefly by sitting for some time and then trying to stand up. She was unable to lift her legs, and attempts to move the thighs brought sharp shooting muscle pains, radiating from hip to knee. At the same time she noted a dull aching pain in the thigh muscles at intervals of about a month, which lasted three to five days. About one month before admission she developed a feeling of fullness and pressing down in the rectum, which was especially noticeable after sitting for some time. Bowel movements did not relieve the sensation. She had had a three-day episode of watery diarrhea with a small amount of blood. She had had night sweats for one year, which were said to be due to the onset of the menopause.

Nine years before entry it was discovered that the patient's serum gave a positive serologic test for syphilis; the spinal fluid was negative. She received antisyphilitic treatment for several weeks at that time, and a full course of treatment seven years later. One year before admission she had a left radical mastectomy for scirrhous carcinoma with axillary metastases, which was followed by x-ray treatment.

Physical examination showed a well-developed, fairly well-nourished woman in no distress. The incision over the left breast was well healed, and no evidence of recurrence could be found. The lungs were negative except for a few moist rales at the left base. The heart was normal. The abdomen

was protuberant. There was increased lumbar lordosis. The posterior superior iliac spines were above the anterior superior iliac spines. Examination on standing showed full spinal motion; on flexion and extension from a flexed position, considerable pain was present about the sacrum. There was joint tenderness over the coccyx, over the sacroiliac joints posteriorly and along the attachments of the erector spinae muscles to the sacrum. In the sitting position passive movement of the spine was normal. Straight leg raising was 60° bilaterally, with stretching of the hamstrings. Rectal examination showed tenderness over the coccyx. Neurologic examination was negative.

The blood pressure was 140 systolic, 100 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a white-cell count of 7700. The hemoglobin was 75 per cent. The urine was negative. Blood Hinton and Wassermann tests were negative. The blood sedimentation rate was 5 mm. in fifteen minutes, 38 mm. in thirty minutes, 49 mm. in forty-five minutes and 51 mm. in sixty minutes. A blood calcium was 11.1 mg. per 100 cc., the phosphate 4.7 mg., and the alkaline phosphatase 8.8 Bodansky units. Two lumbar punctures gave clear fluid with total protein of 53 mg. per 100 cc., a gold-sol curve of 0010000000 and a negative Wassermann reaction.

X-ray examination of the chest showed some scarring in the right upper lung field but was otherwise negative. The heart and mediastinum were slightly displaced to the right. Plain and special films of the lower spine revealed an area of rarefaction in the upper margin of the right sacroiliac joint that was surrounded by dense bone (Fig. 1). There was no evidence of disease in the lumbar vertebrae or pelvis. A barium enema was negative.

The aches and pains in the thighs continued. There was considerable weakness. On the fourteenth hospital day the patient developed a slight sore throat and a feeling of exhaustion. The temperature was 102°F. Rales were heard in the left base, with increased bronchophony. The white-cell count was 21,300. Throat culture yielded a beta-hemolytic streptococcus. She was given intravenous fluids and recovered completely from this infection.

On the thirty-fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. THOMAS J. ANGLE: May I see the x-ray films

DR. LAURENCE L. ROBBINS: This is the rather sharply circumscribed area of rarefaction with dense margins that was described. Other than that I do not believe there is anything definite. These areas of calcification are within the abdomen. About the only thing that is at all suspicious is some questionable decalcification in the sacral region.

*On leave of absence.

DR. ANGLEM: Can you tell me more about the nature of the radiating pain that extended down the thighs? Was it sciatic in distribution?

DR. JOHN REIDY: At times she did have a radiating sciatic pain. In the examinations before admission to the hospital the pain had been of that description, but it subsided, particularly after rest in the hospital.

DR. ANGLEM: We have as the essential features of this case a history of pain in the lower back and

slight sore throat. From this she appears to have made a good recovery.

The whole picture is complicated by the fact that the patient is known to have had syphilis in the past, carcinoma of the breast one year before, and x-ray evidence of old pulmonary tuberculosis.

The findings of possible significance are pain referred to the sacral and lower lumbar areas on motion and tenderness on palpation of the sacrum, the coccyx and the regions of the insertion of the

FIGURE 1 Roentgenogram Showing the Area of Rarefaction in the Right Ilum

sacrum of one year's duration, with the development four months later of a radicular type of pain radiating into the lower extremities. The pain appears to have been continuous, with recurring superimposed acute exacerbations of acute pain. Severe shooting pains were induced by lifting the legs one month before admission; the patient developed a feeling of pressure referred to the rectum that was not relieved by evacuation. She had one episode of diarrhea with blood in the stools, which lasted for three days. She had had night sweats for one year, which were ascribed to the menopause but may have arisen on some other basis.

After admission the patient developed a respiratory infection associated with weakness and exhaustion. This is described as a slight sore throat, but the constitutional symptoms seemed to have been severer than those one would expect from a

erector spinae muscles. Also of considerable significance in a negative way is the absence of neurologic signs. The increased sedimentation time and the slight increase in alkaline phosphatase may be of significance, but they are not diagnostic. The increased spinal-fluid protein I believe to be of considerable significance. The x-ray findings may be independent of or related to the patient's present illness.

The symptom complex that this patient presents—pain in the lower back associated with radiation of pain of the radicular type into the lower extremities—is characteristic of a space-occupying lesion in the spinal canal involving the lower spinal nerve roots. Such a space-occupying lesion may arise from a variety of causes. Syphilis should be mentioned because of the patient's past history. It is, however, an uncommon cause of this type of

pain, and since the recent blood and spinal-fluid Wassermann reactions were negative, I believe we can disregard it.

Is there a chest film? The description of the film in the history suggests healed tuberculosis.

DR. ROBBINS: There is evidence of old tuberculosis.

DR. ANGLEM: But no sign of activity?

DR. ROBBINS: Nothing I can be sure of.

DR. ANGLEM: Tuberculosis may produce symptoms of this type when there is tuberculous involvement of the lower lumbar vertebral bodies with extension of tuberculous granulation tissue into the region of the spinal roots. There is, however, no evidence of such involvement in the lumbar vertebrae to support this diagnosis.

The symptoms that this patient presented frequently arise on the basis of a protruded intervertebral disk. The story is characteristic except in certain minor respects — the absence of paresis and of any disturbance of the reflexes, which, however, are not essential for that diagnosis.

The onset is said to have followed a "cold." This cold may have been a nasopharyngitis, which is a not uncommon primary focus from which osteomyelitis develops. A low-grade osteomyelitis of the lumbar vertebrae could produce the symptoms of which this patient complained, through formation of an abscess extending into the epidural space. The x-ray films, however, show no evidence of such a disturbance of the lumbar vertebrae.

I find it difficult to relate the area shown by x-ray in the region of the right sacroiliac joint to this patient's symptoms. It does not have the usual features of metastatic cancer, and in view of its unilateral position and its circumscribed character, I do not believe that it is possible to account for the patient's bilateral symptoms on this basis. I believe we can safely disregard it.

A primary or metastatic tumor involving the cauda equina must be considered. Against a primary tumor are the relatively slow progress of the disease and the complete absence of definite neurologic signs after the duration of a full year. The same argument may be offered against a diagnosis of metastatic tumor. If she had had metastatic disease involving the cauda equina, originating from the breast carcinoma, I should expect it to have progressed more than it had in the course of a year and to have shown evidence of bone destruction by that time. Considering these various possibilities it seems to me that the basis of this patient's complaint was independent of the other diseases of which we have previous knowledge; hence, I believe that she probably had a protruded intervertebral disk.

DR. BENJAMIN CASTLEMAN: Would you like to express an opinion, Dr. Smith-Petersen?

DR. MARIUS N. SMITH-PETERSEN: I know the diagnosis. I, too, belittled the presence of the area

in the posterior iliac crest. I thought that the changes seen in the x-ray film were due to surface changes, which often give an area of increased density surrounding an area of decreased density, but I was willing that the biopsy should be performed.

DR. PAUL ZAMECNIK: When axillary metastases are found, what are the statistics on finding further metastases? I have an impression that they are rather high.

DR. CASTLEMAN: The prognosis is poor in 75 per cent of the cases.

DR. ANGLEM: I considered another possibility, osteoid osteoma, based on the description and the appearance of the lesion in the sacroiliac area, but I did not see how the other symptoms could be explained on that basis.

DR. CARROLL B. LARSON: We explored the sacroiliac region for the lesion that was seen by x-ray and we came down on an absolutely circumscribed area, as shown in the x-ray. A cross section of this area revealed a cellular-appearing homogeneous pinkish-gray material. I could make nothing out of it grossly. We excised the lesion entirely, and in so doing we uncovered a portion of the sacral side of the sacroiliac joint, including the cartilage. The trabeculation in the anterior body of the sacrum appeared abnormal. I cannot tell why, but it just did not look right, so I scooped out some of the material, which was very friable, and sent it as a separate and distinct specimen from the lesion in the ilium.

CLINICAL DIAGNOSIS

Osteochondroma of ilium.

DR. ANGLEM'S DIAGNOSIS

Protruded intervertebral disk.

ANATOMICAL DIAGNOSES

Metastatic carcinoma of sacroiliac region.
Fibrous dysplasia of ilium.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The microscopic examination of the material scooped out of the sacrum showed metastatic carcinoma. The well-circumscribed lesion in the ilium proved to be an area of fibrous dysplasia completely surrounded by metastatic cancer, but there was no carcinoma within the cyst-like area. The cancer, therefore, was not seen on the x-ray film.

CASE 30122

PRESENTATION OF CASE

A sixty-nine-year-old woman was admitted to the hospital for study.

The patient was rather confused and unable to give an accurate history. She had had rheuma-

ever as a child. Thirteen years before entry she had an episode of jaundice relieved by the removal of the gall bladder, which was said to have contained stones. Five years prior to entry, she had pain in the right flank radiating to the groin, nocturia, urgency, frequency, dysuria and pyuria. These continued off and on, and she was told that she had gravel in the urine. Two or three years before admission she was found to have an enlarged spleen and anemia; she subsequently had frequent attacks of anorexia, nausea without vomiting, gas and abdominal discomfort. One and a half years before admission, following an automobile accident, she developed intermittent attacks of dizziness, vertigo, tinnitus, headache, diplopia, soreness of the neck and tremors. One year before entry she had epistaxis on several occasions, but had had none since. During the eight months preceding admission she had had frequent loose, dark, watery stools, which had recently become normal following her use of Peptobismol. She had had ankle edema and dyspnea on exertion for several years, but these had increased in severity during the last few months before entry, and she developed occasional recordal pain on exertion. During this period she had considerable pain and stiffness in the back, right leg and both arms, and occasionally in the chest. She had lost about 40 pounds of weight over a period of years.

She had had several admissions to the Massachusetts Eye and Ear Infirmary for sinus trouble, bilateral cataracts and other eye troubles.

Physical examination showed a well-developed, rather obese woman in no distress. There was no enlargement of the lymph nodes. She was edematous. The tongue was smooth. The left half of the diaphragm was elevated. The lungs were clear. The left border of cardiac dullness was 12.5 cm. from the midline in the fifth space. The sounds were regular except for occasional extrasystoles. A loud harsh systolic murmur was heard at both the apex and the base, but chiefly in the aortic area. A mitral diastolic murmur was also heard by one observer. The aortic second sound was greater than the pulmonic. The abdomen was protuberant and diffusely tender. A large mass was present in the region of the spleen, extending anteriorly to the midline and five fingerbreadths below the costal margin. The mass was smooth, movable, ballotable and tender, and moved with respirations. There was some tenderness in the left costovertebral angle. Pitting edema of the ankles and sacrum was present. Neurologic examination was normal except for diminished vibration sense in the left leg and absent ankle jerks.

The blood pressure was 146 systolic, 90 diastolic. The temperature was 98.6°F., the pulse 80, and the respirations 20.

Examination of the blood showed a red-cell count of 3,680,000, with 64 per cent hemoglobin. The

white-cell count was 2200, with 64 per cent neutrophils, 32 per cent lymphocytes and 4 per cent monocytes. The platelets were diminished in number, and the red cells were hypochromic. The urine was cloudy, with a pH of 7.5 and a specific gravity of 1.012. There was a + test for albumin, and 1 or 2 red cells per high-power field in the sediment. The stools were guaiac negative. The nonprotein nitrogen was 10 mg. per 100 cc., the blood calcium 10.1 mg., and the phosphorus 1.6 mg. The phosphatase was 4.1 Bodansky units. A blood Hinton test was negative. The blood protein was 6.6 gm. per 100 cc., the albumin being 3.4 gm. and the globulin 3.2 gm. The van den Bergh test was normal.

X-ray examination showed the heart to be enlarged to the left. There was some fullness in the region of the left auricle. The lung roots and fields were not unusual. A large mass was seen in the left abdomen; this was separated from the kidney but not distinguishable from the spleen. The left kidney was somewhat larger than usual. There was an opacity in the right upper quadrant the nature of which could not be determined. There were hypertrophic changes in the spine.

X-ray films of the skull were not remarkable. A barium enema revealed normal filling of the colon. The splenic flexure was displaced anteriorly by an enlarged spleen. A gastrointestinal series was negative except for several longitudinal varices in the lower esophagus. An intravenous pyelogram was somewhat unsatisfactory because of the previous barium. No definite stones could be seen, and except for a slightly low position of the left kidney, no evidence of disease of the urinary tract was observed.

After the first day or two, the patient complained of pain and burning on urination. The urine was found to contain innumerable white cells. A culture gave many colonies of colon bacilli. On the eighth day she was given 4.5 gm. of sulfadiazine, followed by 2 gm. daily for the next three days, at the end of which time the urine had cleared up considerably. The white-cell count was 1800, with 65 per cent polymorphonuclears, 27 per cent lymphocytes, 6 per cent monocytes and 2 per cent eosinophils. The platelets were still decreased in number. The hemoglobin was 7.5 gm. per 100 cc. On the fifteenth day a cephalin flocculation test was +++++ in twenty-four hours and +++++ in forty-eight hours. The prothrombin time was 28 seconds (normal, 18 seconds). The hematocrit was 34 per cent. There was 60 per cent retention of bromsulfalein at the end of forty-five minutes.

The patient was given intramuscular injections of liver extract, 15 units daily. On the eighteenth day she had a severe shaking chill with a fever of 101°F. In the next two days she had colicky pain in the right costovertebral angle and flank. She was nauseated but did not vomit. Examination

showed extreme tenderness in the right-costovertebral angle and flank. One urine examination gave a ++ test for albumin, with a specific gravity of 1.010 and innumerable red cells. An examination on the following day showed large numbers of white cells.

On the twenty-first day the patient had a chill with elevation of temperature to 106.4°F. A blood culture yielded colon bacilli in both flasks. The white-cell count was 1500, and the red-cell count 3,190,000 with 7.5 gm. of hemoglobin. She was given a transfusion of 500 cc. of blood, followed by sulfadiazine for the next two days. The temperature remained elevated, and the pulse became irregular, rapid and of poor quality. There were basal rales. She was given 4 cc. of Cedilanid intravenously, and intravenous saline in glucose and sodium sulfadiazine, but died on the twenty-third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER M. JONES: One of the things that impresses me is that more and more at these conferences we are getting patients farther along in life, thus increasing the necessity for a multiplicity of diagnoses. Many different things happened to this woman that ought to be remembered in the subsequent events. She had had rheumatic fever, jaundice, gallstones, renal colic, an enlarged spleen and anemia. There is also a good description of the symptoms of a subdural hematoma. One year before entry she had epistaxis on several occasions, which is just one more item that adds to the confusion of the story. She had had loose stools, which possibly were tarry, and finally, symptoms of pericardial pain, exertional dyspnea and pain in the extremities and chest. The cataracts and other eye troubles are further evidence of degenerative disease.

It seems to me that with this clinical story it is simply a question of adding up the facts and presenting them as probabilities. I do not see any reason for assuming that there was some rare condition. She had had rheumatic fever and presented the physical signs that are consistent with old, healed mitral stenosis. She is said to have had a mid-diastolic murmur, which is characteristic of this condition.

DR. PAUL D. WHITE: What about the aortic valve?

DR. JONES: She could have an old rheumatic involvement of the aortic valve as well. There is no story of a thrill, transmission of that murmur or a wide pulse pressure.

According to her testimony she had gallstones, which gallstones were removed, and she had jaundice in one of the attacks preceding operation. At entry, the x-ray studies are said to have shown a homogeneous mass in the right upper quadrant whose nature could not be determined. I cannot

do any better than to guess that that might conceivably have been a gallstone that was still in the common duct. The most that I can say is that she had had gall bladder disease in the past — gallstones and jaundice — and had the makings of chronic intrahepatic disease because of the persisting attacks.

There is a perfectly good story of renal stones, and there is no reason to think that the patient did not have them. She had pain in the right flank radiating to the groin, nocturia, frequency, urgency and pyuria. There was evidence of urinary-tract disease during her stay in the hospital, in that she had pain and tenderness in the right costovertebral angle, right pleural pain, a shaking chill, and urine that contained on one occasion red cells and on another pus. There were colon bacilli in the urine, and it is not unreasonable to think she had a urinary-tract infection arising from gravel or stone in the right kidney, which could logically explain the signs and symptoms she showed in the hospital. Whether the hematuria was due to an intrarenal tumor is a matter of pure speculation.

She was said to have had an enlarged spleen and anemia three years before she came in, and I see no reason to doubt that — in other words, she may have had so-called "Banti's disease" as a result of thrombosis of the splenic vein. There is, however, no episode to suggest such a diagnosis. The finding of Banti's disease in a person of her age is unusual. Therefore, it seems to me wiser to admit that she had something more than involvement of the splenic vein, in which case one wonders about intrahepatic disease — cirrhosis of the liver with splenic enlargement. We know that she had esophageal varices by x-ray and also leukopenia, findings that go with any chronic serious intrahepatic lesion even when the disease is relatively quiescent. A splenic tumor fits in with chronic liver disease, and varices can be associated with portal hypertension rather than with thrombosis of the splenic vein. On the basis of the laboratory findings we know that there was a serious intrahepatic complication: the cephalin flocculation test was ++++, there was marked dye retention and the prothrombin time was increased.

The attack of dizziness and vertigo, a year and a half before admission, following the automobile accident, makes me wonder if she had concussion and a subdural hematoma. At any rate these symptoms date from the accident. The nosebleeds may have been due to focal venous engorgement or she may have had marked hypertension, which she did not have on arrival at the hospital. One would have to guess rather than state that she had hypertension. The dark watery stools I cannot explain, unless one wants to say that she was bleeding from esophageal varices.

The patient had precordial pain on exertion, ankle edema, dyspnea and shortness of breath, and it seems

reasonable to suppose that they were cardiac in origin. She was sixty-nine years old when she developed the symptoms, and they appear to have been associated with a degenerative process—namely, arteriosclerotic disease involving the coronary vessels as well as other vessels in the body. She probably had arteriosclerotic disease in addition to the old mitral lesion.

The pain and stiffness in the back, right leg and both arms and the pain in the chest are general complications that occur in any older patient who is "aching all over." She undoubtedly had degenerative changes in the bones, and I assume that she had hypertrophic arthritis. That could explain the aches and pains that she noted from time to time. The loss of 40 pounds of weight over a period of years, and not just during the year prior to admission, I tie in with generalized arteriosclerosis, chronic intrahepatic splenic disease and possibly inadequate diet, along with some degree of heart failure. She had a smooth tongue, diminished vibration sense and absent ankle jerks. If these findings are correct, they are consistent with vitamin deficiency.

The elevation of the diaphragm on the left can be explained by the enlarged spleen. The heart was enlarged to the left. As I have already mentioned, there was a systolic murmur at the base and a diastolic murmur characteristic of mitral disease at the apex. I suppose that might be an Austin-Flint murmur, but I am inclined to doubt it.

The white-cell counts were consistently low. That is consistent with the chronic intrahepatic disease and splenic enlargement, sometimes called "Banti's disease," although I think that the term should be reserved for those cases that have primary disease in the spleen rather than in the liver. The red cells were hypochromic, a fact consistent with bleeding from the gastrointestinal tract. The nonprotein nitrogen was low, and there was fixation of the specific gravity of the urine—1.010 to 1.012. Undoubtedly there was renal involvement of a degenerative nature, possibly with infection. On the other hand, a low nonprotein nitrogen is consistent with serious liver disease. The albumin-globulin ratio was approximately 1.0, also suggesting liver disease. The spleen was enlarged both by physical examination and by x-ray. I should like to look at the films. Did any of them show a gallstone or a large mass in the right upper quadrant?

DR. MILFORD SCHULZ: This shadow probably represents a calculus in the lower pole of the kidney.

DR. JONES: Then I withdraw the remark about gallstones. This picture is quite different and should have been mentioned in the original description of the x-ray findings.

DR. JOSEPH AUB: Is the left kidney enlarged?

DR. SCHULZ: Both kidneys are good sized, and I do not see any real deformity of the calyces. All the bones of the pelvis and spine seem to be intact.

The evidence of mitral disease apparently was more prominent when observed fluoroscopically than is shown on the film.

The films of the gastrointestinal tract show an essentially normal stomach, but in the esophagus there are definite varices. I assume that the films of the skull were taken because of the previous head injury or possibly for examination of the bones.

DR. JONES: From these films it seems to me that there is no reason to change any of the possibilities except to add one as a probability rather than a possibility. I agree with Dr. Aub that the left kidney looks enlarged.

What happened in the hospital is of interest. The patient had an episode of right-sided renal pain with costovertebral tenderness, and I assume that she probably had a calculus, with resulting blood in the urine, fever and chills. Because of that fact it seems reasonable that the shadow in the region of the right kidney is consistent with stone. Is that not correct, Dr. Schulz?

DR. SCHULZ: Yes; it seems to be in the lower calyx.

DR. JONES: The patient had a story of previous renal colic, probably with infection. We know that she eventually developed terminal sepsis and that colon bacilli were found in the urine.

What are the conditions to be found in this woman? I think that she had old rheumatic heart disease with mitral involvement, and probably generalized arteriosclerosis with involvement of the heart. It is quite possible that arteriosclerotic heart disease rather than rheumatic heart disease was of more importance in relation to the heart failure and precordial pain on exertion. She had degenerative changes in the spine. She probably had cirrhosis of the liver with a relatively small liver and an enlarged spleen and resulting portal hypertension and esophageal varices. She did not have a primary hepatoma on top of the cirrhosis. I do not see how one can avoid the evidence of real interference with hepatic function and I do not believe it was entirely on the basis of cardiac failure. She undoubtedly had some changes in the right kidney, probably pyelonephritis as well as arteriosclerotic changes. I do not know the cause of the apparent renal enlargement on the left. There was no hydronephrosis. The ureter was not noted to be enlarged, and on the x-ray films its shadow appears to be normal. Is that correct, Dr. Colby?

DR. FLETCHER H. COLBY: From here the renal outline appears to be fairly large but not irregular. There is no depression of the calyces that I can see. I do not believe that there was a renal tumor.

DR. JONES: To say that she had a tumor is simply a guess to explain an unusual finding in the kidney. I think that she had right renal colic from a renal calculus, with resulting infection. I do not believe that she had gallstones.

DR. AUB: Could she not have some widespread degenerative disease, such as amyloidosis?

respiratory infections, and there was no significant difference in the average duration of illness in the two groups. The total number of organisms recovered in periodic throat cultures made in the sulfadiazine-treated children was not less than that in the controls. Some types of organisms were entirely unaffected by the drugs, whereas others were strikingly reduced in number, particularly the gram-negative cocci (*Neisseria*). After one month of treatment, however, these organisms again increased, and sulfadiazine-resistant strains were encountered. Similar changes were noted among pneumococci. In the control children many types of pneumococci were encountered continuously throughout the study. In the treated group, on the other hand, the same multiplicity of types was noted at first but within a short time only two types dominated. Tests showed that these two types had become sulfadiazine resistant, and shortly thereafter these same sulfadiazine-resistant strains of pneumococci had spread into the throats of the control group of children, who were housed in the same cottage.

The results of these investigations suggest another possible danger, and a serious one, from the prolonged use of sulfonamide drugs in prophylaxis or treatment. The question is raised whether these drug-resistant virulent strains will eventually lead to infections that are difficult to manage and to control. The development of such strains during the treatment of disease has already been encountered.³ Julianelle and Siegel correctly point out that further studies are needed to determine whether these drug-resistant strains really constitute a practical hazard in the prolonged use of the sulfonamides.

SURVIVAL OF THE FIT

CHANGES in the environment, sometimes slow, sometimes rapid, and the adaptation of life to them, are being constantly demonstrated, and natural history, so far back as discoverable records go, shows

that those forms of life that could not adapt themselves to changes in their surroundings had perished. The sabre-tooth tiger and the mastodon, once lords of the terrain over which they roared, are known to us only through crude, prehistoric drawings and an occasional pile of mud-encrusted bones; the giant saurians, maintaining themselves on the lush vegetation of the muck age, succumbed when these conditions changed, and have left us to remember them by, only their skeletons and a gigantic footstep.

It is important to note, however, that no biological order has completely disappeared from life. We have tigers and elephants and lizards, but of different varieties and characteristics suited to their continued existence in the medium in which nature left them, so long as that medium remains suitable to them. The working theory of the survival of the fittest has seen to it that the correct animal was left to graze in its proper pasture; that a suitable vegetation succeeded in the soil and climate best adapted to it; that those organisms hardy enough to withstand the inimical forces of nature are the ultimate survivors until, perhaps, some new influence requires a greater refinement in the strain or allows a newly originated species to flourish.

Thus in the vegetable kingdom we find resistant strains of wheat and other food crops and flowers; blight-resistant chestnuts are appearing after the apparent destruction of our chestnut some years ago. The human race is developing resistance, perhaps owing both to mass immunization and to natural selection, to many of the infectious diseases that have variously scourged the world. Syphilis, although still an ubiquitous plague, is not so sear as it did when it was first visited on our kind; tuberculosis finds fewer victims and ravages them less fiercely than when consumption took its toll of the last few centuries — an improvement is not entirely due to better hygiene and to better finding; and measles is a relatively minor annoyance among conditioned populations, as compared with the havoc it can raise on virgin soil, such as existed on Pitcairn and among the Faroe Islanders.

Even as we develop our immunities and our weapons for defense, however, our biologic enemies adapt themselves to the new conditions with w

challenge them, and the battle is never entirely won. Even new and better chemical agents will not win the last word against infectious disease, valuable as they have proved themselves to be, for the human body may become sensitized to them, and drug-resistant strains of various pathogenic organisms put in their appearance. Cases of pneumococcal pneumonia are encountered, for example, that do not respond to sulfonamide therapy, and the incidence of gonococcal infections that are resistant to mothyral is appreciable. The same, no doubt, will be true with penicillin and every other agent that we may develop. The struggle is unremitting.

MEDICAL EPONYM

DARIER'S DISEASE (PSEUDOXANTHOMA ELASTICUM)
Jean Darier (b. 1856), of Paris, presented a paper "pseudoxanthoma elasticum" at the Third International Dermatological Congress in London during August, 1896. A German translation of this paper, by Dr. Turkheim, of Hamburg, appeared in the *Monatshfte für praktische Dermatologie* (23:609, 1896). A portion of the translation follows:

There is a disease of the skin, apparently of rare occurrence, with clear, unmistakable anatomic and clinical symptoms that can be termed "pseudoxanthoma elasticum." This disease expresses itself clinically by the formation of macules, plaques or yellowish papules that have great similarity to those of true xanthomas.

Anatomically, the disease finds its expression in a disruption with swelling and finally disintegration of the elastic tissue into absolute crumbs. . . . On the other hand the specific metamorphoses of xanthoma, xanthomatous cells and fat granules are missing.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE TO AID THE STRICT RATIONING OFFICER

Requests for extra rations on medical certificates of patients' necessity, above and beyond the basis fixed to which the population as a whole has cheerfully submitted, continue to come in to the local rationing boards at a fairly steady rate. Those that exceed certain established maximums or concerning which any particular question is raised are usually referred to the regional Office of Price Administration to be passed on by the advisory medical committee.

Some rationing boards, such as the Brookline board, have appointed local medical advisory committees; such a course, if widely followed, would serve to lighten considerably the load of the regional office, especially if existing formulas were accepted as a spirit of co-operation. It must be re-emphasized that the advisory committee of the Massachusetts Medical Society is desirous only of helping to apply

the principles of food rationing in such a way that as little hardship as possible will be inflicted on anyone. Furthermore, it believes that basic rationing as it applies to the majority of persons carries no hardship.

It has been possible at last to obtain reasonably accurate figures on the number of persons obtaining extra ration allowances from one large community—Somerville. In that city, 0.5 per cent of the population is receiving supplementary food allowances—on the whole, not a staggering proportion of the residents.

The alluring diagnosis of anemia is assuming increasing prominence as a reason for the prescription of extra rations, especially red meats and liver. In reference to this situation, it must be pointed out that anemia is not included in the legitimate extra-point diseases listed by the Subcommittee on Medical Food Requirements of the National Research Council; that hematologists have ventured the opinion that iron and liver extract are more effective antianemic substances than is meat; and that in England liver is considered too precious to use as food, being reserved for the preparation of liver extract for the treatment of hyperchromic anemia.

JOSEPH GARLAND, *Chairman*

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

WEISSMAN—Robert J. Weissman, M.D., of Bristol, died February 1. He was in his thirty-third year.

Dr. Weissman received his degree from the University of Vermont College of Medicine in 1937. He first interned in Louisville, Kentucky, before setting up a practice in Richmond and Montpelier, Vermont. Dr. Weissman had been in Bristol about three years.

His widow and mother survive.

MISCELLANY

WARREN TRIENNIAL PRIZE

The Warren Triennial Prize, which was founded by the late Dr. J. Mason Warren in memory of his father and which carries an appreciable honorarium for the best dissertation, considered worthy of a premium, on some subject in physiology, surgery or pathology, was recently awarded by the General Executive Committee of the Massachusetts General Hospital to David G. Cogan, M.D., V. Everett Kinsey, Ph.D., and Erwin O. Hirsch, B.A., for their essay entitled "Physiologic Studies on the Cornea." The paper "Studies on Traumatic Shock," by Everett I. Evans, M.D., received honorable mention.

CORRESPONDENCE

ATHEROSCLEROSIS

To the Editor: How difficult the task of making plain to the generality of the profession the significance of retained cholesterol esters is going to be is indicated by the reaction of a brilliant man like Dr. Roger I. Lee (Geriatrics: The medical care of the elderly. *New Eng. J. Med.* 230: 190-193, 1944) to the thesis that this agent is the cause of atherosclerosis. Let me say in the beginning that the term "atherosclerosis" is not mine. Recognition of the distinctive character of the disease goes back to Virchow and Aschoff. The contradictory name atherosclerosis (literally, mushy hardening) goes back to Marchand. The term is not limited in its application to "premature and devastating arteriosclerosis." It is applied to the important form of arteriosclerosis that is probably responsible for at least 90 per cent of clinical and pathologic manifestations of arteriosclerosis as such.

The sterols are evidently necessary to life since they are found in all living cells, animal and vegetable. Cholesterol is one of the most complex substances found in the animal body (Schoenheimer). It is so complex that we do not know how it is metabolized. We do know, however, that its metabolism is difficult, and that when the substance is present in excess it is precipitated in crystalline ester form in the tissues and is treated as a foreign body. It is engulfed by phagocytic cells and is carried in these cells into the arterial intima. The characteristic that differentiates atherosclerosis from other forms of arterial disease is the presence in its lesions of crystals of excess cholesterol, usually in ester form, and visible under polarized light. We do know that excess ester cholesterol is a chronic irritant comparable to silica sol. We do know that excess cholesterol satisfies all of Koch's postulates as the cause of atherosclerosis.

Dr. Lee makes much (or little) of the use of the rabbit for experimental purposes. The old criticism that the rabbit suffers an artificial disease because we introduce into its diet an animal fat to which it is not accustomed does not carry much weight when one remembers that much of the knowledge we have of human infection and immunity arose from the introduction into rabbits of bacteria or toxic agents to which they were not accustomed. It is also to be remembered that the rabbit synthesizes this same animal fat (cholesterol) for the needs of its own cells. Moreover atherosclerosis has been produced in chickens by adding excess cholesterol to their diet (Dauber, D. V., and Katz, L. N. Experimental cholesterol atherosclerosis in an omnivorous animal. *Arch. Path.* 34:937-950, 1942). As a matter of fact the principal function of rabbit experimentation has been to satisfy Koch's postulates and to clear up the *modus operandi* of excess cholesterol activities. Our basic knowledge of the causation of the disease is due to the study of the specific relation of excess cholesterol esters to the lesions of human atherosclerosis, and is particularly due to the following of the disease sequence (Sydenham's footsteps of disease) from beginning to advanced stages in some thousands of human lesions.

Cholesterol is the forerunner of the cortical adrenal secretion. It is the probable source of the bile acids and the sex hormones. Its degradation products include known carcinogens. A retained excess of cholesterol is potentially dangerous. There is evidence of its pathogenic action in the human body in addition to the causation of atherosclerosis. Excess cholesterol is manifestly a substance that should be destroyed or excreted. We are able to metabolize it in youth, as is shown by its removal from the ester deposits in the aorta in the atheromas of infancy and puberty. It is this ability that prevents the production of atherosclerosis in the arteries of youth.

As we age we lose the power to control cholesterol. There is no longer a metabolism that can destroy the excess, and no excretory machinery that can remove it from the body. It remains within the body and is responsible for the production of the condition that led Dr. Lee to conclude: "No, that isn't wear and tear; that is just rust." Modern industrial chemistry is demonstrating new methods to prevent rust. It is my expectation that modern medical methods, no longer influenced by the "abandon hope" attitude adopted in so-called "modern" texts on geriatrics, will find means of preventing or controlling the "rust" that can kill men even in the twenties and thirties from coronary disease, and

can lift cardiovascular renal disease and cancer to a of domination of the causes of death as early as the f

CANDIDATES FOR INTERNSHIPS

To the Editor: At a recent meeting of the War Post Committee of the Massachusetts Medical Society Edward A. Knowlton, of Holyoke, raised an in question. He asked how hospitals approved for training should attempt to procure interns.

Under the accelerated program and the 9-9-9 plan all medical students who are in their final year, e to graduate in the fall of 1944, have been appointed t ships that will begin about October 1 and will en July 1, 1945. A number of hospitals already are begi scrutinize, as potential intern candidates to succee third-year medical students, who so far have had than a few months' exposure to clinical work of any:

The Boston Interhospital Internship Commit decided to hold on October 16 to 19, 1944, its examin the next group of internships available under its juri This committee considers it unsound to examine: didates until they have completed at least three full medical education. Not before then can they be to have had enough clinical work to be in a position the type of internship that they wish to undertake; before then can their teachers have a valid opinion co their ability as clinicians.

The internship is such an important part of medic tion and interns are such an essential part of hospi cency that their proper selection under war condit most important step. Their premature appoint unnecessary and does not seem sensible.

"HOLMES AS A PSYCHIATRIST"

To the Editor: My attention has been called to statements in the editorial *Holmes as a Psychiatrist* published in the February 3 issue of the *Journal*.

The first relates to the date of the address given by before the Phi Beta Kappa Society at Harvard. used, 1871, was based on a statement by Oberndorf essay *The Psychiatric Novels of Oliver Wendell*. Actually the lecture was given on June 29, 1870, a stated on the title page of the printed address, w not published until 1871. Editions were issued Boston and London in that year, and the address printed, with a new title page, in Boston in 1872.

The editorial stated, moreover, that the address, " held from publication for more than twenty years, after careful revision, expansion and annotation h place, did Holmes allow it to appear in print." above, this statement is entirely incorrect. The add printed not only once but a number of times, and ap Holmes made no effort to suppress it himself. W debted to Mr. F. Franklin Currier, the bibliogr Holmes, moreover, for calling attention to a state Holmes in a letter to a classmate: "The sale and of my little book have been quite a surprise to a hardly expected it to pay for itself but so far it remarkably well."

The writer of the editorial misinterpreted a state Oberndorf, who wrote that the essay "was carefully expanded, and annotated before it was printed: from an *Old Volume of Life*." This reference sho been verified and not taken to mean that the add not published immediately after it was given. O moreover, is not correct in saying that the add "revised, expanded, and annotated" before it was Even in the 1883 edition of *Pages from an Old Volum* the article contains few revisions.

I am indebted to Dr. George R. Minot for cal attention to these errors.

A CLINICAL EVALUATION OF SULFAMERAZINE*

DONALD G. ANDERSON, M.D.,† CHARLES S. OLIVER, M.D.,‡ AND CHESTER S. KEEFER, M.D.§

BOSTON

THE purpose of this report is to present the results of the treatment of 278 patients with sulfamerazine. This sulfonamide derivative is 2-sulfanilamido-4-methyl pyrimidine (sulfamethyldiazine). Its chemistry has been described by Roblin, Williams, Winnek and English¹ and by Sprague, Kissinger and Lincoln.² In spite of the fact that preliminary studies of experimental infections in animals indicated that sulfamerazine is fully as active as sulfadiazine, it did not until recently receive the attention it deserved.

From the studies of Welch, Mattis, Latven, Benson and Shields³ and others,⁴ it became apparent that sulfamerazine might have certain advantages over sulfadiazine, provided it could be shown to be as effective in the treatment of infection. These advantages were the greater solubility of both sulfamerazine and its acetyl derivative than the respective sulfadiazines, the more rapid and more complete absorption of sulfamerazine from the gastrointestinal tract and its slower excretion by the kidneys.

When equal doses of sulfamerazine and sulfadiazine were given by mouth to normal subjects, Welch et al. were able to obtain and maintain blood levels of sulfamerazine that were on the average more than double the values obtained with sulfadiazine. These observations naturally suggested that blood levels comparable to those obtained in the clinical use of sulfadiazine could be achieved with a considerably reduced total dosage of sulfamerazine, and that adequate blood levels could be maintained with a longer time interval between doses. Finally, in view of the somewhat increased solubility of sulfamerazine over sulfadiazine, it was suggested that fewer renal complications might occur.

In this study, the purpose was to determine the clinical efficiency of sulfamerazine in various infec-

tions, the adequate dosage schedule and the side reactions.⁵

Before presenting the results it is well to say something about the toxicology of sulfamerazine. Extensive studies of this subject by Welch et al.³ in mice, dogs, monkeys and chickens showed that when similar blood concentrations are maintained, the toxic effects of sulfamerazine are no greater than are those that follow the administration of sulfadiazine. Particular importance was attached to the study of neuropathologic changes in chickens. These experiments showed definitely that sulfamerazine produced fewer lesions of the spinal cord and sciatic nerve of chickens than did sulfadiazine. There was therefore no good reason for believing that sulfamerazine is more toxic to the nervous system than is sulfadiazine.

Preliminary studies of toxicity in man by the same investigators revealed no unusual toxic reactions. This finding has been further supported by similar but more extensive studies by Clark et al.⁶ These authors, after administering sulfamerazine to 200 patients, concluded that sulfamerazine is probably no more toxic than the sulfonamides now in common use.

CLINICAL MATERIAL AND METHODS

In the present study, sulfamerazine was administered to 278 patients with bacterial infections. Two hundred and ten of these patients were adults, and 68 were children under twelve years of age.

As a general rule, adults were given 2 gm. initially, followed by 1 gm. every eight hours thereafter. In children weighing 60 pounds or more, the same dosage was followed. In children weighing less than 60 pounds, the initial dose was usually 0.5 gm. and

the daily maintenance dose was computed on a basis of 0.5 gm. for each 10 pounds of body weight and was given in three equally divided doses at eight-hour intervals. In most of the cases the oral route was exclusively used. In a few severely ill patients, particularly those with meningitis, the sodium salt of sulfamerazine was given intravenously as a 5 per cent solution in distilled water during the early part of their illness. Occasional modifications of the above dosage schedule were necessary. Among the adult cases, the dosage was increased in 17 cases and reduced in 27.

Daily determinations of free and total sulfamerazine were performed on samples of whole blood in most of the cases, and at frequent intervals in the remainder. The method of Bratton and Marshall⁶ was used for these determinations.

Efforts were made to keep the daily urinary output above 1200 cc. In a few cases equal quantities of sodium bicarbonate were given with each dose of sulfamerazine, but this procedure was not followed in the majority of cases.

There was no fixed policy with regard to the duration of therapy. In general, sulfamcrazine was continued for a period of forty-eight to ninety-six hours after apparent clinical recovery and the disappearance of fever.

CLINICAL RESULTS

Pneumonia

Eighty-nine patients were treated for pneumonia. In 46 of these the causative organism, as judged by the blood culture or sputum examination, was a pneumococcus, and in 4 it was a beta-hemolytic streptococcus; in the remaining 39 the blood cultures were negative and the organisms cultured from the sputum were not considered to be related to the infection. Of the entire group, 7 patients died, giving a mortality rate of 8 per cent. Of the remaining 82 patients, a clear-cut therapeutic response was observed in 77.

Pneumococcal lobar pneumonia. Forty-four adult patients presenting the typical clinical picture of lobar pneumonia were found to have typable pneumococci in either the sputum or the blood or in both (Table 1). Analyzed from the point of view of factors influencing prognosis, this group of patients was closely similar to the series of sulfonamide-treated pneumonia cases that have been reported by other investigators.⁷⁻¹² Fourteen patients (32 per cent) had involvement of more than one lobe. Twelve patients (27 per cent) had bacteremia. Twenty-four patients (54 per cent) were fifty years of age or older. Five patients (11 per cent) were chronic alcoholics. Seven patients (16 per cent) had organic heart disease with cardiac failure and 5 (11 per cent) suffered from a variety of significant systemic disorders, including diabetes, myxedema, pulmonary tuberculosis and carcinomatosis. For those who recovered without complications, the average dura-

tion of treatment was seven days and the average total dosage was 20 gm. The average blood level maintained through the course of therapy varied from 4 to 17 mg. per 100 cc. of free sulfamerazine and from 5 to 19 mg. of total sulfamerazine.

Four of the patients had received either sulfathiazole or sulfadiazine before entry to the hospital.

*All deaths occurred in patients having bacteremia.
†This patient did not respond to sulfamerazine, but subsequently recovered after treatment with penicillin.

These patients were still acutely ill, one of them with a positive blood culture, at the time sulfamerazine therapy was instituted. Three patients received type-specific antiserum in addition to sulfamerazine; 2 died; and 1 developed an empyema.

Thirty-six patients recovered promptly and without complications. Eighteen were afebrile within forty-eight hours; and in 6 more the temperature was normal at the end of seventy-two hours; in the other 12 the temperature fell by lysis over a longer period of time. None of these patients relapsed. Figure 1 shows the chart of a patient who responded promptly to therapy.

Of the remaining 8 patients, 4 eventually recovered. One of these had delayed resolution, experienced a massive sterile pleural effusion, developed an empyema requiring surgical drainage, and the fourth, who was still acutely ill after seven days of therapy, was given penicillin and subsequently recovered.

Four patients died, giving a mortality rate of 9 per cent. The first patient was a seventy-four-year-old man with carcinoma of the prostate and generalized metastases. He was admitted on the fifth day of illness in severe cardiac failure and died four hours later. The blood culture was positive for Type 14 pneumococcus. The second patient was a fifty-year-old man who was admitted with a blood culture positive for Type 4 pneumococcus and a leukocyte count of 1350, no granulocytes being seen on smear. He was given specific antiserum and seemed to be improving until the third day. Atrial fibrillation with pulmonary edema then developed, and he died on the fourth day, apparently

cardiac failure. The third patient was a forty-two-year-old man admitted on the third day of his disease. The blood culture on admission was positive for Type 4 pneumococcus. He was given specific antiserum as well as sulfamerazine, but failed to improve and died in peripheral circulatory collapse on the third hospital day. The fourth patient was a forty-two-year-old man who was admitted on the seventh day of his disease, with a history of chronic alco-

Of these 17 patients, 15 recovered without complications and 2 died. The first death occurred in an eighty-four-year-old man who on entry appeared to be in extremis. X-ray examination showed consolidation of both the left upper and left lower lobes. The patient received 17 gm. of sulfamerazine over a period of six days. Although the signs in the chest had begun to clear, the general condition deteriorated and he died on the sixth day of therapy. The second fatality was in a sixty-eight-year-old man who entered the hospital in congestive heart failure, with a temperature of 104°F. and signs of consolidation of the right lower lobe. He received sulfamerazine for three days, during which time the temperature fell to normal; however, he became progressively more stuporous, lapsed into coma, and died on the third hospital day. No autopsy was obtained in either case.

Streptococcal pneumonia. Four patients with pneumonia caused by a beta-hemolytic streptococcus were treated with sulfamerazine. Three recovered and 1 died. Two of the patients were children in whom the pneumonia was secondary to scarlet fever. The other two were adults in whom the pneumonia was apparently primary. Both children recovered. One of them developed an empyema that had to be drained surgically. This patient received sulfamerazine for twenty-five days, at the end of which time thoracotomy was performed, and the drug was discontinued because of a sharp drop in the white-cell count with depression of the granulocytes. The second child developed a sterile pleural effusion that eventually resolved spontaneously. He received sulfamerazine for twenty-six days, becoming afebrile on the twenty-third day of therapy.

Of the two adult patients, the first was a man fifty-two years of age who had been hospitalized for mild hypertensive heart disease. His course was without event until the end of the third week, when he had a shaking chill, with a rise in temperature to 105°F., and developed signs of pneumonia. Blood culture showed a beta-hemolytic streptococcus. He was given sulfamerazine, with a prompt return of the temperature to normal in twenty-four hours. Although a transient secondary rise of temperature to 102°F. occurred on the fifth day, he had completely recovered after nine days of therapy.

The other adult patient was a sixty-five-year-old man who had been ill for five days before entry. On admission there were signs of pneumonia in the right lower lobe. Culture of the sputum showed an almost pure growth of beta-hemolytic streptococci. Three blood cultures were sterile. On the fourth day of treatment, fluid appeared in the right pleural cavity. Culture of this fluid also showed a beta-hemolytic streptococcus. The patient received 3 gm. of sulfamerazine daily for ten days, during which time the blood levels of the uncombined drug ranged between 5 and 10 mg. per 100 cc. He failed to improve, however, and death occurred on the tenth hospital day.

Bronchopneumonia. Twenty-two patients with bronchopneumonia were treated with sulfamerazine. In 2 patients pneumococci were recovered from the sputum. In 20 patients no causative organism could be isolated from the blood or sputum. Sixteen of these patients were adults and 6 were children. All

FIGURE 2. Chart of a Patient with Meningococcal Meningitis Who Responded Rapidly to Treatment with Sulfamerazine.

the patients recovered, although 2 of them relapsed and required a second course of chemotherapy before recovery was complete.

For the adult patients, the average duration of treatment was six days, and the average total dosage of sulfamerazine was 15 gm.

Primary atypical pneumonia of unknown etiology. Two patients who presented the characteristic features of this syndrome¹³ were treated with sulfamerazine. One received 12 gm. in five days, and the other 32 gm. in seven days. Both had blood levels of free sulfamerazine averaging 7 mg. per 100 cc. In neither case was there any evidence that sulfamerazine was beneficial.

Meningitis

Meningococcal meningitis. During the current epidemic of meningococcal meningitis, there has been

an opportunity to treat 50 patients suffering from this disease with sulfamerazine. Although many of these patients were desperately ill, all recovered. This series of patients is to be reported in detail elsewhere. Figure 2 shows the chart of a patient with meningococcal meningitis who responded rapidly to treatment with sulfamerazine.

Two patients who had meningococcemia without meningitis were treated with sulfamerazine and recovered. One of these patients, through error, received only 2 gm. of the drug and yet made a complete recovery.

Hemolytic streptococcus meningitis. One patient, a six-year-old girl with meningitis caused by a beta-hemolytic streptococcus, was treated with sulfamerazine. During the course of scarlet fever she developed acute otitis media on the right side. Five weeks after the onset of the scarlet fever, a simple mastoidectomy was performed. Convalescence was uneventful until four weeks later, when the mastoidectomy incision was revised because of persistent drainage. The patient then remained well for seventeen days, at the end of which time there was a sudden rise in temperature to 102.6°F., accompanied by the appearance of the signs of acute otitis media on the left side. Two days later, drowsiness and marked rigidity of the neck appeared. Lumbar puncture revealed a purulent fluid from which beta-hemolytic streptococci were cultured. The blood culture was sterile. The patient was given 2.5 gm. of sodium sulfamerazine intravenously and placed on oral dosage. Forty-eight hours after the beginning of treatment she was asymptomatic. Recovery was complete.

Pneumococcal meningitis. One patient, a two-month-old boy with meningitis due to Type 7 pneumococcus, was treated with sulfamerazine. At the time treatment was begun the patient had been ill with fever for four days but had had meningeal signs for only one day. The initial response was favorable, the temperature returning to normal in four days and remaining normal for the next six days. Sulfamerazine was discontinued on the ninth day. Two days later, the temperature rose to 103°F. The drug was resumed and the patient was given sufficient specific antiserum to produce an excess of circulating antibodies in the blood. No improvement resulted, however, and death occurred forty-eight hours later. Autopsy revealed massive amounts of exudate about the base of the brain and over the cerebral hemispheres.

Other Infections

Erysipelas. Twenty-one adult patients with facial erysipelas were treated with sulfamerazine. These patients were all moderately to severely ill, although none had positive blood cultures. In 15 cases the admission temperature was 101°F. or higher, 6 patients having temperatures above 103°F. The dosage of sulfamerazine was 2 gm. initially, followed

by 1 gm. every eight hours. In one case the maintenance dose was 0.5 gm. every eight hours. The average duration of treatment was four days, with an average total dosage of 12 gm.

The response to treatment with sulfamerazine was clear cut and extremely satisfactory (Fig. 3). All the patients recovered. Within twenty-four hours of the

Subacute bacterial endocarditis. Four patients with subacute bacterial endocarditis due to *Streptococcus viridans* superimposed on rheumatic valvulitis were treated with sulfamerazine. Three of them were treated late in the course of their disease for periods ranging from six to twenty-two days. Blood levels of free sulfamerazine between 6 and 9 mg. per 100 cc. were maintained. No significant improvement, either subjective or objective, occurred.

The fourth patient had been ill for only a month when therapy with sulfamerazine was instituted. On a dosage of 4 gm. a day she maintained a blood level that was consistently in the neighborhood of 15 mg. of free sulfamerazine per 100 cc. and 18 mg. of total sulfamerazine. After ten days of therapy, the blood cultures became sterile and remained sterile for twenty days. At the end of this time, they became positive again and remained so, although sulfamerazine was continued for another nineteen days, together with fever therapy and neosarsphenamine.

Infections of the urinary tract. Ten patients were treated with sulfamerazine for infections of the urinary tract — too small a number for statistical analysis. Of these, 4 had acute pyelonephritis. *Escherichia coli* alone was cultured from the urine of two patients and *Esch. coli* and *Staphylococcus aureus* from the urine of the other two. All four of these patients became asymptomatic on a daily dose of 3 gm. of sulfamerazine for periods varying from four to seventeen days. Only 1 patient was severely ill. This was a fifty-one-year-old man who had had dysuria for four weeks and chills and fever with back pain for one week before entry. On admission he was acutely ill; the temperature was 102°F., and there was marked tenderness in the left costovertebral angle. Blood and urine cultures were positive for *Esch. coli*. Therapy consisted of 3 gm. of sulfamerazine daily for eleven days. After seventy-two hours, the temperature did not rise above 100°F. and the patient felt greatly improved. At the end of a week, he was afebrile and asymptomatic.

Four patients were treated for acute cystitis. Three recovered completely after receiving sulfamerazine for periods varying from four to eight days. In the fourth case, therapy had to be discontinued after thirty-six hours because of vomiting, which was primarily due to causes other than chemotherapy.

One patient who was moderately ill with acute prostatitis and acute epididymitis following the use of an indwelling catheter made a satisfactory recovery in the course of ten days of therapy. One patient with chronic pyelonephritis was treated for three weeks without showing significant improvement. Urine cultures showed *Staph. aureus* and *Esch. coli*.

Acute otitis media. Forty patients with acute otitis media were treated with sulfamerazine. In 36 cases the otitis media was secondary to scarlet fever, in 2 to measles, and in the remaining 2 to nonspecific upper respiratory infections. Thirty-one patients

FIGURE 3. Chart Showing Prompt Response to Therapy with Sulfamerazine in a Patient with Facial Erysipelas.

beginning of therapy, all showed marked subjective improvement. In 10 patients defervescence had occurred within this period, and in 10 of the remaining 11 patients the temperature became normal by the end of forty-eight hours. The last patient had a marked acute cervical adenitis as well as facial erysipelas. The temperature did not return to normal until the end of the fifth day. No significant extension of the lesion took place in any case after therapy was instituted, and in the majority of cases resolution of the lesion was practically complete at the end of four days. The hospital stays varied from four to ten days, with an average of seven and a half days.

were children. The total dosage in this group was variable. The average blood levels maintained during the course of therapy varied from 3 to 17 mg. of free sulfamerazine per 100 cc. and from 5 to 20 mg. of total sulfamerazine.

Each patient was given a trial course of sulfamerazine for one week. If definite improvement, as evidenced by a decrease in the amount of discharge, was observed by the end of this time, the drug was continued until the ear became dry. If no improvement was observed, the drug was discontinued. The duration of treatment varied from three to eighteen days, with an average of seven days.

The results of treatment do not lend themselves well to evaluation, since no attempt was made to observe a control series. Of the 40 patients, 35 had an aural discharge either as the result of paracentesis or of spontaneous rupture of the tympanic membrane at the time sulfamerazine was started. In 22 (63 per cent) of these patients the ear became dry during treatment. In 13 (37 per cent) drainage persisted at the time sulfamerazine was discontinued. Six patients eventually required mastoidectomy.

Treatment was begun in 5 patients while the otitis was still in the catarrhal stage. In all these cases, the infection resolved without the occurrence of drainage.

Acute tonsillitis, peritonsillitis and cervical adenitis. This is another group of patients in which, because of the lack of adequate controls, satisfactory evaluation of results is not possible. Five patients with acute tonsillitis showed defervescence within twenty-four hours of the beginning of sulfamerazine therapy, and marked improvement in both local and constitutional signs by the end of forty-eight hours. Two patients with severe peritonsillitis showed a satisfactory response to therapy. Fever disappeared within forty-eight hours, and local signs had completely subsided by the end of five days. Two patients with severe cervical adenitis secondary to scarlet fever showed satisfactory resolution of the adenitis after seven and nine days of therapy, respectively.

Staphylococcal infections. In addition to the 3 patients with pyelonephritis due to staphylococci, 7 others suffering from staphylococcal infections were treated with sulfamerazine. Two of these patients had bacteremia due to a hemolytic *Staph. aureus*.

The first patient was a forty-five-year-old woman with monocytic leukemia who developed a persistent bacteremia seventeen days before her death. She received 3 gm. of sulfamerazine daily for two weeks, on which dosage she maintained an average blood level of 10 mg. of free sulfamerazine per 100 cc. The blood cultures remained positive, and no clinical improvement was detectable.

The second patient was an eighty-three-year-old man with arteriosclerotic heart disease and cardiac failure who developed a *Staph. aureus* bacteremia five days before death. It was at first thought that he

was suffering from a cystitis secondary to the use of an indwelling catheter. He was accordingly started on a dosage of 0.5 gm. of sulfamerazine every eight hours. When the blood culture was reported positive twenty-four hours before death, the dosage was increased to 1 gm. every eight hours. A blood culture taken shortly before death was still positive for *Staph. aureus*.

Two elderly diabetic women with early gangrene of the toes developed cellulitis of the lower extremities due to *Staph. aureus*. Sulfamerazine was given in one case for twenty-two days and in the other for twenty-five days. Both patients continued febrile, and although the infection did not show significant extension during therapy, neither did it show any tendency to resolve. Mid thigh amputation was eventually necessary in both cases.

Two patients with large abscesses due to *Staph. aureus*, one of the breast and the other of the buttock, were placed on sulfamerazine shortly before incision and drainage was performed. Both recovered uneventfully, but there is no evidence that sulfamerazine played any role in their recovery.

The last patient was a fifty-year-old man who had an undrained Brodie's abscess of the right femur that had developed two years previously following bacteremia due to *Staph. aureus*. For several days before the present entry he had been ill with spiking fever and painful induration of the soft tissues of the thigh. *Staph. aureus* was cultured from pus aspirated from the indurated area. Three grams of sulfamerazine was given daily for eight days, the blood level of free sulfamerazine being maintained consistently in the vicinity of 10 mg. per 100 cc. During therapy the temperature continued to spike as before, and the local lesion definitely increased in extent. Sulfamerazine was discontinued after eight days.

Acute sinusitis. Four patients with severe acute sinusitis received sulfamerazine. In 3, there was prompt and permanent improvement in both local and constitutional symptoms. The fourth patient was a ten-year-old girl who developed a severe right ethmoiditis during the course of scarlet fever. Treatment with sulfamerazine was not begun until the sinusitis had been present for five days. Despite adequate blood levels of the drug, she did not improve, and four days later surgical drainage was performed, following which recovery was uneventful.

Gonococcal urethritis. Only 1 patient suffered from a gonococcal infection was encountered during this study. This patient, a twenty-four-year-old man, had had an active urethritis for six weeks. Two courses of sulfathiazole and a course of local irrigations had not cleared the infection. The patient was hospitalized and put on complete bed rest for thirteen days, during which time he was given 45 gm. sulfamerazine. By the end of that time the discharge had ceased. Urethral smears and cultures were negative. When the patient was seen five weeks after discharge, there had been no recurrence.

In addition to the 239 cases that have been discussed, 39 additional patients were given sulfamerazine. In most of them the presence of an infection susceptible to the action of chemotherapy was suspected but never satisfactorily established. In the remainder, the use of multiple therapeutic measures made proper assessment of the role of sulfamerazine impossible and the therapeutic response could not be adequately evaluated. These patients, however, are included in the section on toxicity.

TOXIC REACTIONS

Excluding uncomplicated crystalluria, toxic reactions were observed in 70 (25 per cent) of the patients treated. For the most part, these reactions were mild and not of a character to jeopardize the patient's health or cause severe discomfort. The incidence of toxic manifestations in this series is somewhat higher than that reported by Clark et al.⁵ In Table 2 are summarized all the reactions observed in the present series. Included in the number of patients showing

Joint pains	1	0.4
Conjunctivitis	1	0.4

crystalluria are 36 who showed uncomplicated crystalluria as the only manifestation of toxicity. These patients are not included in computation of toxicity for the whole series.

Nausea and vomiting. Eighteen patients (6 per cent) experienced nausea, and 12 of these vomited. The vomiting was never severe or protracted. It interfered with the continuance of oral therapy in only 1 patient, and in this case the vomiting was due primarily to causes other than chemotherapy.

Headache. Three patients complained of moderate headache that could reasonably be attributed to the use of sulfamerazine. In only 1 did the symptom persist throughout therapy.

Toxic psychosis. Five patients developed marked mental confusion that was presumably caused by sulfamerazine. In all the cases it came on within forty-eight hours after the first dose of drug and persisted until it was stopped. The blood levels were not unusually high in any case. All these patients were acutely ill with high fever at the time chemotherapy was started. In 4 cases there was a definite history of previous psychiatric abnormalities. The fifth patient was a senile woman of seventy-eight.

In all cases the mental confusion cleared completely one to three days after stopping the drug.

Anemia. A significant degree of anemia that could not be attributed to the underlying disease appeared in 3 patients during the course of therapy. In each case there was a gradual fall in the red-cell count and hemoglobin over a period of six to eight days. The average decrease in hemoglobin was 3 gm., and the red-cell count fell an average of 1,400,000. No cases of acute hemolytic anemia were encountered.

Leukopenia. The effect of sulfamerazine on the white blood cells deserves special mention. A fall in the leukocyte count to below 4000 was observed in 8 patients. In 4 cases, the fall occurred only after therapy lasting from fifteen to twenty-five days. Two of these patients showed a marked granulocytopenia, whereas in the other 2 the normal percentage of granulocytes was maintained. One of the patients showing granulocytopenia was reported to have developed a white-cell count of 2000 with 50 per cent neutrophils several weeks previously after five days of sulfadiazine therapy.

The 4 other patients showed leukocyte counts of less than 4000 cells after periods of therapy ranging from five to twelve days. Three of these showed no depression of the granulocytes. The fourth was a patient with monocytic leukemia who had shown only 1 or 2 per cent granulocytes for several weeks before sulfamerazine was started. Her total white-cell count at the time therapy was started was 126,000. By the ninth day of therapy it had gradually fallen to 3400. Sulfamerazine was continued for another six days, during which time the count fluctuated between 4000 and 8000. Two days after sulfamerazine was discontinued, it had risen to 20,000. Despite the marked changes in the total count, no significant changes in the differential count occurred, nor was there any detectable change in the course of the leukemia, which terminated fatally three days after treatment was stopped.

In all the above cases except the last, sulfamerazine was discontinued as soon as the leukopenia was discovered, and in 6 cases the white-cell count returned to normal a few days after chemotherapy was stopped. The seventh patient was an infant with pneumococcal meningitis who was moribund at the time the leukopenia developed and died shortly thereafter. The leukopenia in this case may well have been caused by the overwhelming infection and not by the drug.

Thirty-one other patients showed white-cell counts between 4000 and 4950 during therapy. These low counts were found mostly toward the end of the first week of sulfamerazine administration or during the early part of the second week. In 5 patients who had received the drug for periods ranging from five to twelve days, there was a moderate decrease in the percentage of granulocytes. In the other 26, the granulocytes showed no decrease. In 10 of these 31 patients sulfamerazine was continued for several

more days after the appearance of leukopenia. Before chemotherapy was discontinued the white-cell count had returned to normal levels.

Judging from this experience, it appears that sulfamerazine can cause leukopenia and granulocytopenia after prolonged therapy in a manner similar to that of the other sulfonamides. It further appears that a definite decline in the white-cell count is not infrequently seen after shorter periods of drug administration. Inasmuch as no ill effects occurred in the present series when the drug was continued under such circumstances, the appearance of a moderate leukopenia near the end of the first week of therapy with sulfamerazine should probably not be a cause for alarm, particularly if there is no depression of the granulocytes. Continuation of therapy, if indicated, appears to be a safe procedure, although the white-cell count should be followed carefully.

Toxic manifestations involving the urinary tract. Although sulfamerazine is significantly more soluble than sulfadiazine, its solubility is still sufficiently poor so that complications involving the urinary tract are to be looked for. Evidence that this is so was found in the present series. Crystalluria, which by itself is not generally considered to be significant, occurred in 60 patients (21 per cent). Doubtless, if all voidings had been examined, the incidence would have been much higher.

Microscopic hematuria, a more significant finding, was seen in 20 patients (7 per cent). In 10 of these cases there was an associated crystalluria, whereas in the other 10 no crystals were seen. Gross hematuria occurred in 2 patients. In one case renal colic accompanied the hematuria; in the other, the hematuria was painless. In both cases it cleared a few hours after the drug was stopped and fluids were given. One other patient had transient flank pain. In this case there was massive crystalluria without hematuria.

One patient developed anuria on the sixth day of therapy. There had been no antecedent crystalluria or hematuria, but the output for the preceding two days had fallen gradually. When anuria occurred, the drug was stopped and fluids were given orally and parenterally. The first specimen voided after the period of anuria contained large numbers of crystals but was not otherwise abnormal. After twenty-four hours a satisfactory flow of urine was established. Sulfamerazine was then resumed and was continued for two more weeks without further ill effect.

Drug rash. Fourteen patients (5 per cent) developed a rash while receiving sulfamerazine. In 10 patients, the rash was accompanied by fever. A generalized morbilliform rash was the type most commonly seen. In 1 case, conjunctivitis occurred in addition to a morbilliform rash.

Drug fever. Fourteen patients (5 per cent), including 10 of those who had rashes, had fever that

was apparently due to the drug. This complication appeared between the seventh and eleventh days, and tended to be of a low grade, the temperature rising above 102° F. in only 1 case (Fig. 4). Associated constitutional symptoms were, as a rule, not severe. With discontinuation of the drug, the

FIGURE 4. Chart of a Patient with Cervical Adenitis Who Developed Drug Fever on the Seventh Day of Therapy with Sulfamerazine.

temperature returned to normal within twenty-four to seventy-two hours. One patient had multiple joint pains with slight swelling of the wrists and knees at the time the fever began. The drug was stopped, and he became symptom-free within twenty-four hours.

COMMENT

The evaluation of sulfamerazine as a chemotherapeutic agent may be approached most satisfactorily by comparing it with sulfadiazine. A comparison of these two compounds with respect to therapeutic efficiency can best be made from an analysis of the results obtained in the treatment of pneumococcal pneumonia, meningococcal menin-

gitis and erysipelas. The conditions encountered in these diseases are sufficiently standardized, and the experience with sulfadiazine in their treatment has been sufficiently uniform, to make the results the basis for a valid preliminary comparison.

Pneumococcal pneumonia. In pneumococcal pneumonia, the mortality rate of 9 per cent is of the same order as that reported by investigators using sulfadiazine (Table 3). The incidence of complications of pneumonia in the present series was likewise com-

Meningococcal meningitis. Fifty consecutive cases of meningococcal meningitis were treated with sulfamerazine without a death. In the first report on the use of sulfadiazine in this disease, Dingle, Thomas and Morton¹⁶ treated 13 cases, with 1 death. Subsequently, Hodes and Strong¹⁷ reported the treatment of 10 patients with no deaths, and Rundlett and her co-workers¹⁸ the treatment of 23 cases with no deaths. Feldman et al.¹⁹ had 2 deaths in 24 cases. It is clear that sulfamerazine is a potent and efficient

TABLE 3. Comparison of Mortality Rates in Pneumococcal Pneumonia Treated with Sulfamerazine and with Sulfadiazine.

Number of cases	44	178	80	200	239	105	115
Mortality rate (per cent)	9	10.7	7.5	12.0	10.9	7.6	11.3

parable to those reported for the sulfadiazine-treated cases.^{7, 9, 10, 12} The rapidity of response to therapy is more difficult to compare. Fifty per cent of the patients who recovered without complications following sulfamerazine were afebrile at the end of forty-eight hours. Finland and his group⁷ reported that 75 per cent of their patients were essentially afebrile within thirty-six hours of the first dose of the drug. Dowling et al.¹² state that in 68 per cent of their cases the temperature was normal within forty-eight hours, whereas Flippin et al.⁹ reported the temperature to have become normal in 55 per cent of their patients by the end of forty-eight hours.

A comparison of the average total dose of sulfamerazine used in the patients with pneumococcal pneumonia who recovered with the average total doses used in the sulfadiazine-treated cases is of interest. The impression gained from the preliminary investigations of the absorption and excretion of sulfamerazine that a smaller total dosage would be required than with sulfadiazine was well borne out.

An average total dose of 20 gm. of sulfamerazine was administered to the patients who recovered. Finland and his associates^{7, 8} have reported average total doses of 42 gm. and 38 gm. of sulfadiazine for those recovering in two groups of patients. Flippin¹¹ reported an average total dosage of 27 gm. It is of interest that Domm and others,¹³ in treating 25 patients with sodium sulfadiazine by the intravenous route alone, gave an average total dose of 20 gm.

From the foregoing analysis, it appears reasonable to conclude that in the treatment of pneumococcal pneumonia sulfamerazine shows an effectiveness similar to that of sulfadiazine. Furthermore, it appears that the total dosage necessary for adequate treatment of this disease is about one half to one third less than the amount of sulfadiazine ordinarily used.

agent in the treatment of meningococcal meningitis, equaling if not surpassing sulfadiazine.

Erysipelas. Twenty-one patients with erysipelas treated with sulfamerazine made prompt and complete recoveries. Finland and his colleagues^{7, 8} have reported a total of 64 cases of erysipelas treated with sulfadiazine with equally satisfactory results. In the present series, the average total dose of sulfamerazine was 12 gm., whereas in Finland's cases the average total dose of sulfadiazine was 27 gm. It appears, therefore, that in the treatment of erysipelas sulfamerazine equals sulfadiazine in efficiency, and that the average total dose of sulfamerazine is about half that of sulfadiazine.

Staphylococcal infections. The results obtained in the treatment of staphylococcal infections with sulfamerazine were not encouraging. The cases treated, however, were not of a type to afford a particularly fair trial for the drug. A greater experience will be necessary before an opinion can be formed about the effectiveness of sulfamerazine in infections caused by staphylococci.

Toxic reactions. A comparison of sulfamerazine with sulfadiazine on the basis of toxicity is also necessary. In Table 4 the toxic reactions to sulfadiazine that have been reported by several investigators are summarized and compared with those encountered after the use of sulfamerazine in the present series. It can be seen that the incidence of nausea and vomiting in the present series of cases was slightly higher than that usually reported for sulfadiazine. The number of patients developing a toxic psychosis approaches the average incidence of this reaction in the sulfadiazine-treated patients. The appearance of anemia in patients treated with sulfadiazine has been reported only in isolated cases. In the present series, 3 patients developed a mild anemia.

The appearance of leukopenia (a white-cell count below 4000) in 3 per cent of the patients treated with sulfamerazine constitutes a definitely higher incidence of this toxic reaction than has been reported for cases treated with sulfadiazine. Further significance may be attached to this finding when it is recalled that an additional 31 patients (11 per cent) showed a fall in the white-cell count to between 4000 and 5000. It appears, then, that sulfamerazine shows a distinctly greater tendency than does sulfadiazine to depress the white-cell count. Whether this property constitutes a serious drawback to the value of

SUMMARY AND CONCLUSIONS

The results of treatment with sulfamerazine patients are presented, together with the toxications manifested by this group and by 39 additional patients during the course of therapy. Sulfamerazine exhibited a therapeutic effect similar to that of sulfadiazine in the treatment of pneumococcal pneumonia, meningococcal meningitis, and erysipelas. Sulfamerazine was clinically effective in doses that were on the average one half to one

sulfamerazine as a chemotherapeutic agent depends on the results of greater experience with the drug. So far, recovery from leukopenia has been prompt and without complication. In our own experience, leukopenia occurring in the first week has been of little consequence, since it frequently disappears even when the drug is continued.

Crystalluria occurred with about the same frequency with both drugs. Microscopic hematuria showed a moderately higher incidence in the patients treated with sulfamerazine. Gross hematuria and renal colic occurred with about the same frequency with both drugs. From these figures, it may be gathered that despite theoretical considerations, sulfamerazine has about the same capacity for causing renal complications as has sulfadiazine.

The incidence of rash and fever in this series is somewhat higher than the figure reported for sulfadiazine but is still not particularly striking in itself.

In summary, it seems fair to say that in general the toxic reactions following the use of sulfamerazine are of about the same character and incidence as those following the use of sulfadiazine. Two exceptions should possibly be made to this statement: first, that sulfamerazine has a greater tendency to cause leukopenia than has sulfadiazine; and second, that the incidence of drug rash and drug fever may be somewhat higher with sulfamerazine. Further experience is necessary before these last points can be fully evaluated.

smaller than the amounts of sulfadiazine administered for similar conditions.

Toxic reactions to sulfamerazine were in general of the same character and occurred with about the same frequency as those caused by sulfadiazine. The greater tendency for sulfamerazine to produce leukopenia and to cause drug rashes and drug fever constitutes a possible exception to this statement.

It may be concluded that sulfamerazine is a valuable chemotherapeutic agent and a valuable addition to the sulfonamide derivatives already in general use.

We are indebted to Dr. William Feirer of Sharp and Doherty Company, Philadelphia, for supplying the sulfamerazine used in this study, to Miss Thelma Maxon and Miss Constance Haynes for technical assistance, and to the house officers of the Fifth and Sixth Medical Services (Boston University School of Medicine), Boston City Hospital, for their cooperation.

ENCAPSULATED PLEURAL EFFUSION DUE TO HEART FAILURE*

A Report of Two Cases

ABRAHAM H. RUSSAKOFF, M.D.,† and TOBIAS WEINBERG, M.D.‡

BALTIMORE

THE occurrence of encapsulated pleural transudation due to heart failure has been reported in the literature in less than 50 cases. The first case, observed by Helm¹ during 1912 and 1913 and proved by autopsy, was published five years later. This author made the observation that serial x-ray examinations of the chest showed marked changes. Sharply delineated shadows extending across a lung field were later demonstrated to have become so indistinct as to defy recognition had one not been acquainted with previous films. Fleischnier,² in his report of 2 cases in 1926, confirmed Helm's observation that alterations in the x-ray shadows accompany variations in the degree of heart failure. Stewart's³ case published in 1928 was followed by the reports of several other American authors.⁴⁻¹²

Because of the paucity of cases on record, the general impression has been that this condition is rare. The report of Bedford and Lovibond¹³ from England, however, indicates that encapsulated pleural effusions due to cardiac failure may be more frequent than recorded heretofore. In a series of 368 cases of heart failure, they found 136, or 35 per cent, with x-ray evidence of simple hydrothorax. Of these 136 cases, there were 11, or 8 per cent, with interlobar effusions.

CASE REPORTS

CASE 1. A 73-year-old, married Jewish woman (SH U-12502-1) was admitted on November 15, 1939, with an infection of the urinary tract. For several months prior to admission, she had experienced repeated attacks of angio pectoris, associated with weakness, dyspnea and cyanosis. The temperature on admission was 102°F. (rectal), the pulse 120, the respirations 38, and the blood pressure 128/68. The positive physical findings were limited to the heart and lungs. The chest was emphysematous without bony deformity. The respiratory excursions were equal on both sides. There was dullness on percussion over almost all of the right base, and over a small part of the left base, posteriorly. Medium moist rales were heard only at the right base posteriorly.

†Formerly, resident in medicine, Sinai Hospital.

‡Pathologist and director of laboratories, Sinai Hospital.

teriorly. The trachea was not deviated. The apical impulse of the heart was palpable in the 5th interspace, 9.5 cm. to the left of the midsternal line. The heart was not considered to be enlarged. The heart sounds were of fairly good quality; the rhythm was regular, and there was a soft systolic apical murmur.

The anemia. for albumin in blood, 11 mg. per 100 cc.

The infection of the urinary tract responded favorably to sulfonamide therapy. During hospitalization the patient had a few attacks of weakness associated with an alteration in the quality of the heart sounds, but without a drop in blood pressure or a change in the cardiac rhythm. An x-ray film of the chest (Fig. 1) showed two distinct circular shadows in the right lower lung field, which were interpreted as interlobar effusions.

The patient was discharged improved after 5 weeks. She is still alive and quite well, but has refused to return to the hospital for physical examination and x-ray examination of the chest.

CASE 2. A 62-year-old, married Jewish grocery clerk (SH U-23500-1) was admitted on July 27, 1942, because of cough, dyspnea and a recent weight loss of 15 pounds. The cough had been productive of frothy white sputum. There had been no thoracic pain, wheezing, hemoptyses, chills or sweats. In 1921, the patient had spent 2 months in another hospital because of painful knees and ankles, which subsided with salicylate therapy. No abnormality of the heart was noted at that time.

On admission, the temperature was 102.4°F. (rectal), the pulse was 100, the respirations 28, and the blood pressure 110/70. The patient was well developed but showed evidence of recent loss of weight. He was dyspneic, orthopneic and cyanotic. The cervical neck veins were distended. The trachea was deviated to the right. The respiratory excursions on the right side were limited. Tactile fremitus was increased on the right and diminished on the left side. There was dullness on percussion in the left axillary region and over both bases posteriorly. Medium moist rales were heard in the right axilla and posteriorly over the right lower pulmonary field, extending up to the angle of the scapula. The precordium was visibly enlarged.

cardiac impulse was 9.0 cm. to the left of the midsternal line. There were no thrills, shocks regular and the heart sounds were of fair quality. A presystolic crescendo murmur was localized over the xiphoid process. The second pulmonic sound was markedly accentuated, and a protodiastolic gallop rhythm was audible at

‡Reported through the courtesy of Dr. Samuel Wolman.

the apex. The liver and spleen were palpable 1 or 2 cm. below the costal margin and were not tender. There was no peripheral edema.

The admission hemogram revealed a mild hypochromic anemia with leukocytosis. The urine was essentially negative. A serologic test for syphilis was negative. The blood

was found. Following this procedure he ran a course characterized by severe dyspnea and a remittent fever. Digitalization effected temporary improvement. On the 9th hospital day, a left thoracentesis was performed and 1000 cc. of clear yellow fluid was removed. The specific gravity of the fluid was 1.010; a cell count revealed 10,000 red cells (probably

FIGURE 1. Anteroposterior and Lateral Views of the Chest in Case 1, Showing Encapsulated Interlobar Effusion.

sugar was 89 mg. per 100 cc., and the blood urea 67 mg. per 100 cc. Studies of the sputum for elastic tissue and for tubercle bacilli and other pathogenic organisms were negative.

An x-ray film of the chest (Fig. 2) taken the day after admission showed an ovoid, opaque shadow in the middle right

due to a trauma) and 300 white cells, with a predominance of mononuclear cells.

The thoracentesis was followed by temporary relief of the dyspnea, but the patient continued to go downhill, with increasing dyspnea, orthopnea, cyanosis, edema of the hands

FIGURE 2. Anteroposterior and Lateral Views of the Chest in Case 2, Showing Encapsulated Interlobar Effusion.

pulmonary field, with pleural thickening along the right base in the axillary line. There was a left pleural effusion. The roentgenologist's diagnosis was probable neoplasm with thickened pleura at the right base and a pleural effusion on the left side. The patient was bronchoscoped, but no tumor

and feces, stupor and, finally, pulmonary edema. On the 15th day, the temperature rose to 105°F. and the patient died.

Autopsy (performed 3½ hours after death). The right pleural cavity was practically obliterated by fibrous adhesions, and the left pleural cavity contained approximate

1100 cc. of clear, straw-colored fluid. The right lung was completely covered by fibrous adhesions. These were found to form a wall for a pocket of fluid situated posteriorly between the upper and lower lobes. Within this pocket, a band of fibrous adhesions extended from the upper to the lower lobe. Another pocket of fluid was found between the diaphragm and the diaphragmatic surface of the right lung. Foci of bronchopneumonia were found in the lower lobe of the right lung, and numerous small infarcts were present in all lobes. Pulmonary edema was marked. The heart was moderately enlarged. There was a rheumatic mitral stenosis associated with dilatation and hypertrophy of the left and right auricles and of the right ventricle. In addition, there was moderate coronary arteriosclerosis, and in association with this a healed infarct of the posterior wall of the left ventricle. The usual picture of chronic passive congestion was present in the liver and spleen.

COMMENT

The anatomy of the potential interlobar spaces and the characteristic roentgenogram of interlobar effusions have been described in a number of contributions.^{5, 11, 14} Suffice it to note that interlobar effusions are characterized by well-defined shadows along the interlobar septums, which may be circular, ovoid, band-shaped or wedge-shaped. It is generally agreed that in some cases a lateral film of the chest is helpful in differentiating this condition from carcinoma, cyst, gumma or abscess of the lung and from marginal pneumonia.

The original concept of the pathogenesis of interlobar effusions due to heart failure is reviewed in Austrian's⁷ article; namely, that with obliteration of the interpleural space due to antecedent infection, there is no other space available in which the effusion can localize. Anatomical investigation has borne out the fact that in some of these cases the interpleural space has been obliterated. In most cases, however, histories of previous pulmonary infections and of pleurisy have been lacking.

Stein and Schwedel⁹ offer an alternative explanation for the cases that show simple hydrothorax in addition to encapsulated effusions. They hold that with simple pleural effusions there may be an indentation at the interlobar fissure, with seepage of fluid from the general pleural cavity into the interlobar spaces. With repeated episodes of heart failure or in chronic cardiac failure — with hydrothorax, there may be organization of fibrin, resulting in pleural thickening. Such a process may go

on to the formation of adhesions between the parietal and visceral pleuras, with subsequent obliteration of the interpleural space. Fluid may then collect only in the interlobar spaces and become encapsulated.

Rigler,^{15, 16} in his x-ray studies of cases with simple pleural effusion, has demonstrated variations in the intensity of interlobar markings that can be altered by changing the position of the patient. He believes that such x-ray changes may be explained by the extension of fluid from the general pleural cavity into the interlobar spaces before encapsulation has taken place. With the deposition of fibrin and subsequent encapsulation of the interlobar effusion, however, changing the position of the patient does not alter the x-ray appearance of the shadow.

SUMMARY

Two cases of encapsulated pleural effusion in association with heart failure are reported.

The various concepts of the pathogenesis of interlobar effusion and the roentgenographic characteristics are reviewed.

MEDICAL PROGRESS

PSYCHIATRY

VERNON P. WILLIAMS, M.D.*

BOSTON

THE partially informed, and possibly gullible, layman often speaks with admiration and awe to the psychiatrist of the "wonderful new field" in which the latter works. The better-informed person, perhaps a physician who is not a psychiatrist, may smile a little wryly about the wonderful new field, thinking of a rather meager fulfillment of the supposed possibilities of psychiatry in regard to progress.

The undertaking of personality problems — mental and emotional disabilities — by a certain branch of medicine does not justify the conclusion that that department of medicine has failed in its intention if permanent cures are not effected in the majority of cases. Psychiatry is attempting to do all that can be done, often against impossible odds. The progress is not disheartening if this is considered.

Neuropsychiatry is much better organized in this war than in the last for responding to the demands made of it — namely, primary elimination of the men unfit for military service, secondary elimination in the early stages of training and treatment of those who break down in combat areas. Shock treatment for the psychoses, although it has not reorganized defective material into permanently healthy material, has hastened recovery and has lessened immediate suffering. Attempts to introduce knowledge of the principles of mental hygiene and an understanding of emotional reactions into elementary education have continued.

SHOCK THERAPY

Insulin and metrazol have now been used in this country over a long enough period — more than seven years — for the treatment of schizophrenia to permit a fairly reasonable evaluation of their effectiveness. Because of the danger of vertebral fracture, metrazol is used less frequently or is employed in combination with insulin.¹ Insulin has proved its value in that it so often shortens the duration of the psychotic attack. It cannot be counted on to prevent relapse.

Some investigators still report that the insulin-shock method results in no higher rate of recovery than is obtained with the more conservative types of treatment. Gottlieb and Huston,² for example, found in the Iowa State Psychopathic Hospital that 66 patients treated with insulin showed no better remission rate than did 132 patients who did not receive pharmacologic treatment. On the other

hand, Bond and Rivers,³ at the Pennsylvania Hospital, consider insulin therapy justified, "with an immediate recovery rate five times that of control cases . . . and with a long-distance recovery rate twice that of controls." Their investigations cover a seven-year period.

Of the drastic measures for treatment of the psychoses, attention has been centered in the past few years on electric shock. As with insulin and metrazol, no promise of permanent cure is offered, but immediately favorable results have frequently occurred. Electric shock has been most successful in cases of depression, both of the manic-depressive and the involutional types. Some workers have reported amelioration in schizophrenia, but in general it is the depressions that have given the best response.

In a follow-up study on 126 patients treated with metrazol and 144 patients treated by electric shock, cases of dementia praecox, manic-depressive and involutional psychosis and psychoneurosis, Pacella and Barrera⁴ say that their statistics "suggest that possibly the electric shock method may be slightly more efficacious, at least in so far as the immediate results are concerned." The metrazol cases were followed for eighteen to twenty-four months and the electric shock cases for six to fifteen months after treatment.

These workers found the results of both types of treatment rather discouraging in the psychoneurotic cases. They consider convulsive treatment of undoubted, great value in the effective psychoses. It is interesting that in the schizophrenic patients only those who had strong affective components, principally of a depressive kind, showed substantial improvement or complete remission.

During a year and a half Reznikoff⁵ treated 100 schizophrenic patients with electric shock. He found a pronounced tendency to relapse, as he had previously found in 100 schizophrenic patients treated with metrazol. He states that electric shock is preferable to metrazol because of the amnesia for the treatment, less fear and anxiety and painless shock in the former.

In regard to fear of electric-shock treatment, Myerson⁶ says:

It is safe to say that the statement made in the literature that there is no fear of the treatment is not correct; there is less than with metrazol shock, and often enough the individual treatment is not at all remembered. In the relatively sane patients, the whole matter of repairing to a hospital, of becoming unconscious and of a period of agitation and loss of memory afterward becomes linked up

*Assistant in psychiatry, Massachusetts General Hospital.

with the idea of treatment, and a definite association fear of the treatment develops. In the markedly psychotic cases, no such fear seems to be experienced.

Favorable response to electric shock, if it occurs, usually follows a comparatively small number of treatments. Sulzbach, Tillotson et al.⁷ have given only two to six convulsive shocks in all their successful cases and have seen no impressive results if the latter have not been obvious after ten treatments. They give treatments twice, rarely three times, a week. Myerson,⁸ in a series of 120 cases, gave seven or less shocks to each patient.

Outpatient or extramural electric-shock therapy has proved practicable in certain cases. Wender, Balser and Beres⁹ report a series of 40 cases so treated. In choosing such procedure, both the psychiatrist and the patient's family have to keep in mind the danger of suicide. The advantages are the preclusion of the expense of hospitalization and of the dread or prejudice of certain patients or their families in regard to hospital admission and care.

Popular and effective, at least temporarily, as electric shock is, it should, of course, not be used indiscriminately. The physical condition of the patient, especially that of his heart and blood vessels, and his age must be considered. It is surprising, however, how well some elderly patients have withstood the rigors of treatment. If the mental illness is particularly severe and intractable over a long period of time, it is fair to estimate the advantages of this treatment against its disadvantages. Evans⁹ gave convulsive treatment, either by electric shock or by metrazol, to a series of patients over fifty years of age, and in a report on the first 50 consecutive cases claims in 40 of them either recovery or enough improvement to permit discharge of the patients to their homes.

Although experimental work on animals has revealed some brain damage, chiefly small hemorrhages, in connection with electric shock, there seems to be no evidence that serious or permanent injury of any disabling degree occurs in the brains of human beings. The confusion and loss of memory, which are typical, are apparently only of a temporary nature.⁶

WAR PSYCHIATRY

The literature, in both neuropsychiatric and general medical journals, is in large proportion composed of an unending number of articles on the psychiatric aspects of war. This is not overemphasis, since such a considerable percentage of the casualties in combat areas alone, roughly 30 per cent, are of a psychiatric nature.

The Army, and to a less extent the Navy, in this country, from the inauguration of required service in the armed forces during the present war, have been alert to the fact that not every man who is physically well and able will make a satisfactory member of the forces. With their knowledge of

psychiatric casualties that occurred in World War I, they have attempted and are attempting to screen out or eliminate before induction the men who seem likely to break down nervously under the circumstances of training and combat. This is no simple undertaking.

The problem centers on this question: With the supposition that an adequate history is at hand for each man examined, if there are data indicating nervous or emotional instability in the past or at present, what are the definitions or interpretations that will give the examining physician sound guidance for accepting or rejecting the man? There is no clarifying answer. In the first place, adequate histories have seldom been obtained in the cases in which they would be most valuable, largely because psychiatric social service has only recently been established in most induction centers. In the second place, psychiatric knowledge and insight do not go to the extent of predicting unfailingly and exactly what degrees and kinds of nervous instability should exclude a man from service.

It is generally agreed that a history of psychotic attacks, long-standing neurotic reactions, — even though only slightly disabling in civilian life, — definite psychopathic tendencies, epilepsy and chronic alcoholism are reasons for rejection. Yet Bigelow¹⁰ has observed that some men with certain neurotic tendencies, anxiety states, conversion mechanisms and hypochondriacal complaints have been successful in military aviation. He proposes that flying may be a symbolic solution of their neurotic conflicts. It should be remembered that in the last war many a neurotic did well as an aviator.

There are, of course, in other branches of the service many men with neurotic tendencies who so far are doing well.¹¹ Whether or not they will later break down may depend on the kind of strain to which they are subjected.

From their experience in a naval hospital, Stearns and Schwab¹² conclude that the Navy has in the past not given sufficient attention to the importance of examining recruits thoroughly enough to exclude undesirable men. They say: "Our unmistakable conclusion is that the military service cannot absorb successfully large numbers of persons who are unable to get along in civilian life. These men should be rejected at the recruiting or . . . induction center."

The presence of a particular neurotic trait is not estimated to be so important as its severity or intensity. Also, the number of traits present in the personality rather than the existence of any one trait is thought by some to be the critical factor. Referring to work done at the Walter Reed General Hospital, Porter¹³ lists fifteen attributes the presence or absence of which are determined in the histories of patients diagnosed as having psychoneurosis or a constitutional psychopathic state. These are as follows:

(1) Bed-wetting beyond four years of age. (2) Thumbsucking or nail-biting beyond six years of age. (3) Failure to engage in competitive games involving risk of injury. (4) Tantrums in childhood. (5) Abnormal shyness or sensitiveness. (6) Preference of playing alone. (7) Repeated grades, difficulty with teachers, chronic truancy in school record. (8) Abnormal fears, such as lightning, dark, bogeyman. (9) Shunning of girls after puberty. (10) Faints. (11) Excessive autonomic system reactions to emotion: tremor, abnormal sweating, tachycardia, etc. (12) Sulkiness under discipline. (13) Abnormal attachment to mother after puberty. (14) Stammering. (15) Obsessional traits.

Porter explains that he and his colleagues believe that the presence of four significant traits is not uncommon in persons who have not become serious military problems, but that the presence of six or more should cause one to prognosticate a probable breakdown under stress. The same type of analysis has been interestingly and cautiously written about by Lewis and Slater.¹³ They dealt with 300 soldiers who were hospitalized for neurotic illness. One hundred and fifty of these were returned to service and were still on duty some months later. The other 150 were discharged. The authors advance the theory that the fewer psychoneurotic attributes the soldier has, the more likely it is that he will remain in the service. They point out, however, that the intensity and quality of the individual attributes have importance in prognosis.

Showing the significance of the relation between a history of nervous instability and later incapacity, Rosenberg and Lambert,¹⁴ in a study of 200 consecutive cases discharged from the Army at Camp Lee, Virginia, found that 100 per cent had symptoms prior to induction. Eighty-two and a half per cent had had symptoms for at least one year before induction, and a little more than 50 per cent had prominent symptoms for more than five years. The authors believe that the majority of these psychiatric casualties could have been eliminated at the induction board if relatively simple social service data had been made available. Gowan,¹⁵ in writing of nervous breakdowns in military service, says that one half to two thirds of the men with such disturbances show definite predisposition.

There are limits of endurance beyond which the strongest and sturdiest of constitutions cannot go without developing psychiatric disabilities. This is well presented by Smith¹⁶ in his description of the casualties among the Marines who fought at Guadalcanal. On the other hand, how remarkably well balanced a group of men can remain in the face of acute but not prolonged horror is depicted by Hogan¹⁷ in his account of the behavior of the crew of the U.S.S. *Wasp* when and after it was torpedoed and sunk.

Disturbing as may be the picture of such a large percentage of psychiatric illness as is occurring in the present war, the military services have become more and more cognizant of the necessity of eliminating, salvaging and educating. The replacement training centers are paying more attention to the organization of neuropsychiatric service, and the

attempt is being made to observe each man closely enough to prevent his leaving the center unless he is judged as fit for line duty. The men who are not so estimated are placed where they can best be used unless it seems obvious that they must be given certificates of disability discharge.^{18, 19}

It is incontrovertible that morale or idealism of some kind shares importance with physical or mechanical factors in determining how well an army, or any other group of men combined for action, does its job. The criticism is heard frequently that the men in the Army and Navy do not know what they are fighting for. Somewhat belatedly and not yet thoroughly enough, the military services are recognizing the extreme importance of training and education beyond the limits of a military manual.

As an example of how effective education in this direction can be, Cohen's²⁰ experiment with a prophylactic mental-hygiene discipline is fascinating, especially to the uninitiated. He was given permission to conduct three series of experiments, involving over 2000 trainees, at two different replacement training centers. The men were divided primarily into two groups, the experimental and the control. These were split secondarily into three groups who were given a number of mental-hygiene talks as part of the training program and three groups who were not given such talks.

The talks covered the following subjects: natural civilian resentments to Army life; regimentation; fear; and a résumé of all adjustment factors. From the day on which the talks began until basic training was completed a record was kept of all sick calls and hospitalizations. Following are the relevant statistics:

First Experiment

Sick calls for psychosomatic symptoms:
Experimental group, 8; control group, 23.
Hospital days for psychosomatic symptoms:
Experimental group, 4; control group, 47.

Second Experiment

Sick calls for psychosomatic symptoms:
Experimental group, 5; control group, 38.
Hospital days for psychosomatic symptoms:
Experimental group, 0; control group, 18.

Third Experiment

Sick calls for psychosomatic symptoms:
Experimental group, 6; control group, 28.
Hospital days for psychosomatic symptoms:
Experimental group, 0; control group, 17.

Promoting and maintaining mental health depends only in part on talks by an instructor. How it works is nicely illustrated in the story of Carlson's Raiders. These 1000 men fought on Guadalcanal and stormed Makin Island. During their exploits only one of them suffered traumatic war neurosis. *Fortune*, in its issue of December, 1943, gives a good description of their integrity and of Lieutenant Colonel Evans F. Carlson's understanding of human needs. Before each raid or attack Carlson discussed with

his men plans, means and reasons. Afterward, causes of failures or successes were also discussed. Quoting from *Fortune*:

Carlson believes that because he prepared the men for what they might expect; because he considered their opinions and feelings; because they were convinced he would never sacrifice a man needlessly; because he provided an outlet for terror and tension; because his men understood what they were fighting for; because the Raiders trusted him implicitly — they suffered virtually no psychiatric casualties.

In the combat areas and in the advanced mobile base hospitals, psychiatry is doing what it can under the circumstances. It hardly needs to be written again that, at least as concerns the health of the individual, treatment should be instituted as soon as possible after symptoms first appear and as near as possible to the geographic point of origin. Under the stress and strain of battle or attack, the first and quick and unwise reaction of some men — unwise from the point of view of future mental health — is to retreat as far as they can from the danger. There is a nice point here, for the mental integrity of some will be preserved only by complete retreat, whereas others underestimate their powers of resistance, just as some people have an overawareness of pain. The experienced and wise psychiatrist, or intuitive line officer, has to make the decision concerning the individual's potentialities for recovery.

The farther away from zones of danger the psychiatric casualty is removed the greater is his resistance to returning, and the more likely is resistance to be manifested by a continuance of his symptoms. Halloran and Farrell²¹ write that the experience of the British in finding that prolonged rest, induced by sedatives if necessary, good food and reassurance given near the front return to duty 70 to 80 per cent of men with acute combat neuroses has been confirmed in American troops.

According to Rome,²² group psychotherapy has been found expedient and efficient in certain advanced mobile base hospitals. It is difficult to imagine that there is much opportunity for psycho-

therapy in most combat areas, and it is known that in many such areas it is possible only to classify and evacuate. As in civilian group psychotherapy, there is benefit for the individual in appreciating that he is not alone in the kind of disability that he might otherwise look on as stigmatizing. As Rome says, "In a group, security is gained by a mutual pooling of insecurity."

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Stated Meeting, February 2, 1944

THE Council of the Massachusetts Medical Society met at John Ware Hall, 8 Fenway, Boston, on Wednesday, February 2, 1944. The meeting was called to order at 10:00 a.m. by Dr. Roger I. Lee, Suffolk, president of the Society. There were 218 councilors present (Appendix No. 1).

The Secretary offered the record of the last meeting as published in the *New England Journal of Medicine*, issue of November 25, 1943.

Dr. John B. Hall, Norfolk, moved its approval. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

REPORT OF AUDITING COMMITTEE

The report (Appendix No. 2) was presented by the chairman, Dr. Fritz B. Talbot, Suffolk.

Dr. David Cheever, Suffolk, moved that the report be accepted and placed on file. This motion was seconded by Dr. Albert A. Hornor, Suffolk, and it was so ordered by vote of the Council.

REPORT OF TREASURER

This report (Appendix No. 3) was offered by Dr. Eliot Hubbard, Jr., treasurer.

He said that the revenues of the Society for the year 1943 were \$7175.36 less than in 1942 and that this was largely explained by reason of the Society's policy of remitting the dues of those of its members who were in the services of the Nation.

He said that, under the advice of investment counsel, the yield of the General Fund had increased from 1.90 to 2.40 per cent and that of the Building Fund from 1.90 to 2.95 per cent, the total of the latter fund being \$66,566.69. He added that the total expenses for 1943 were \$33,133.02, as compared with total expenses of \$48,680.85 for 1942. The Society ended the year 1943, he concluded, with total assets of \$250,385.47.

It was moved by Dr. Hornor that the report be accepted with thanks. This motion was seconded by Dr. Cheever.

Dr. Carl Bearse, Norfolk, thought that the advance sheets distributed by the Treasurer should show the investments in more detail. Dr. Hubbard replied that he would be glad to supply such information if it was the councilor's wish.

The motion was adopted by vote of the Council.

REPORT OF EXECUTIVE COMMITTEE OF THE COUNCIL

The report was offered by the Secretary.

He spoke of the activities of the Committee Appointed to Consult with Representatives of the Other New England State Medical Societies Regarding

the Wagner-Murray-Dingell Bill. He particularly referred to a statement prepared by an informal group of physicians from the six New England states and added that the Executive Committee of the Council authorized the President and Secretary, in the name of the Massachusetts Medical Society, to send this statement in the form of an open letter to the Massachusetts representatives in the Congress of the United States.

The Secretary called the councilors' attention to the fact that this statement appeared in the advance sheets of information and that the statement itself would be presented later in the meeting as part of the report of this special committee.

The Secretary spoke of a memorandum received on December 23, 1943, from the Office of the Surgeon General of the United States Army, which stated in part, "This office will no longer recommend the appointment of graduates of Middlesex College of Medicine as commissioned officers in the Medical Corps, Army of the United States." He also referred to an article printed in the *Boston Herald*, issue of December 22, 1943, in which C. Ruggles Smith was quoted as saying that the probable reason for this action on the part of the Surgeon General was pressure from the American Medical Association. The Secretary spoke of a letter received from Dr. Olin West, secretary of the American Medical Association, in which any such activity on the part of this Association was denied.

The committee reviewed the reports of the Committee on Finance and the Postwar Loan-Fund Committee and approved both, recommending that certain parts of the report of the Committee on Finance be clarified.

The committee reviewed the report of the Committee on Cancer and noted that this committee was not in accord regarding its recommendations to the Council anent certain new regulations issued by the Massachusetts Department of Public Health for the direction of state-aided cancer clinics. It further noted that the majority of the committee recommended that the regulations be approved pending a six months' trial and that from this view the minority dissented. The committee referred the report back to the Committee on Cancer with certain memoranda originating in the Massachusetts Department of Public Health and supplied by Dr. Elmer S. Bagnall, president-elect.

The report acknowledged the receipt by the committee of a letter from Dr. Sidney C. Wiggin in which the latter requested that there be set up in the Massachusetts Medical Society a Section on

Anesthesiology. The Secretary reported that the committee recommended adversely in this matter, and moved the adoption of this recommendation. The motion was seconded by a councilor.

Dr. William A. R. Chapin, Hampden, said that there were many reasonable arguments advanced in Springfield in favor of the establishment of such a section and that it was a pity that there was not someone present to direct the debate in this direction. He added that he was sorry to see the matter go by default. Dr. Peirce H. Leavitt, Plymouth, expressing a similar viewpoint, said that if the anesthesiologists had the ambition to establish a Section on Anesthesiology they should be given the opportunity to go ahead. The Council, on a show of hands, adopted the recommendation of the committee.

The report referred to a communication from the Michigan State Medical Society in which the latter urged that the Massachusetts delegates to the House of Delegates of the American Medical Association be instructed to support a resolution calling for the establishment of an information bureau in Washington, D. C. The Secretary said that the committee recommended that this matter be left, without instruction, in the hands of the Massachusetts representatives in the House of Delegates, and moved the adoption of this recommendation. The motion was seconded by Dr. Charles C. Lund, Suffolk. Dr. Hyman Morrison, Norfolk, asked that the resolution be read. At the request of the President, the Secretary said that this resolution appeared on pages 17 and 18 of the advance sheets of information. The Secretary added that, when a similar matter was before the Council last May, the Massachusetts representatives were sent to the meeting of the House of Delegates uninstructed and that, as an observer at the meeting, the wisdom of this action was very apparent to him. The recommendation was adopted by vote of the Council.

The report spoke of certain appointments that had been made by the President since the last meeting of the Council and of their approval by the committee.

The Secretary moved the adoption of the report as a whole. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

REPORTS OF COMMITTEES

Committee on Publications — Dr. Richard M. Smith, Suffolk, chairman.

The report (Appendix No. 4) was offered by the chairman, who in glowing terms spoke of the work of the editor, Dr. Robert N. Nye. He added that, under the latter's management, the *Journal* had become one of the outstanding medical publications in this country.

The report said that the total number of subscriptions as of December 30, 1943, was 11,909 plus 347 copies sent once each month to the members of

the New Hampshire Medical Society and that the outside subscriptions had been greatly increased, with the result that, although there had been many cancellations during the year, the net increase was 2704.

The report said that the financial operations of the *Journal* for the year had been very satisfactory, the net loss being \$5,852, as compared with a net loss of \$17,550 in 1942.

The report spoke of the employment of a new printer who took over on January 1, 1944, and said that this had been made necessary for many reasons.

The shortage of paper, the report continued, represented a problem that was being met in several ways. In respect to this matter the report went on to say that it may be necessary to cut the weight of the paper or the pagination or both.

Seventy-seven per cent of the papers submitted for publication were accepted.
